# PREFACE

TO

## THE SEVENTH EDITION

---

IN preparing the present edition the text has been carefully revised, and many changes or emendations, scarcely likely to be observed by the casual reader, have been introduced. The more important modifications will be found in the sections relating to paralytic affections of the larynx (in correcting which I have to acknowledge the kind assistance of Dr. SEMON), to hæmic murmurs in heart and murmurs in vessels, to pernicious anæmia and diseases of the mouth and fauces, to paroxysmal hæmoglobinuria, to the physiology of the nervous centres, to tetanus, and to the legal management of lunatics, the information given in which has been made conformable to the requirements of the Lunacy Act 1889. For this I have to thank Dr. PERCY SMITH, Medical Superintendent of Bethlem Royal Hospital. Also brief notices of ‘dry mouth,’ and of ‘acromegaly,’ have been added.

13 OLD BURLINGTON STREET,  
*April, 1890.*

## PREFACE TO THE FIRST EDITION

---

IN placing this work before those for whom it was especially written, namely, the junior members of the profession and students in Medicine, I may be permitted to make a few preliminary remarks, partly by way of explanation, partly by way of acknowledgment, partly apologetic.

The first thought, as I suppose, of everyone who sits down to write a scientific book is bestowed upon the arrangement of his matter. It was my first thought. The classification of diseases, moreover, is a subject to which I have devoted a good deal of attention. But I had long formed the opinion that it is impossible, in a work on Medicine, intended to be practical, to arrange diseases on strictly scientific principles; and in this opinion further consideration of the matter only confirmed me. Consequently the arrangement which I have adopted is for the most part artificial, and to be defended only on grounds of convenience. Certain affections I have grouped together as 'Specific Febrile Diseases'; but all others, with in many cases more or less disregard of accuracy, have been classified as 'Local Diseases.' I may add that, in respect of the diseases of individual organs, I have for the most part arranged them, though without expressly indicating the fact, in the following order, namely: Inflammations, Morbid Growths (including Tubercular and Syphilitic Formations), Parasitic Diseases, Degenerations, and Mechanical and Functional Affections. I have not hesitated, however, in many instances to depart from this arrangement.

The selection of subjects to be discussed in a treatise intended to occupy a moderate compass is by no means easy. Medicine is inextricably interwoven with Surgery and with what it is now fashionable

to term 'Gynæcological Medicine.' Moreover, several other departments of practice, especially perhaps Insanity, are now relegated to specialists, and have attained such importance as to need special hospitals, and to have a literature of their own. And again, many diseases, and more particularly local diseases, which doubtless have a substantial existence, are either not recognisable by specific symptoms during life, or are of very trivial importance, so that it would be a waste of time and space even to enumerate them. I trust that, under such circumstances, I shall be pardoned for having treated some important subjects superficially; for having omitted many subjects which it may seem to some persons that I should have included in my work; and for having occasionally introduced topics which may appear to be beyond the sphere of Medicine, in the restricted sense of that term.

In discussing each subject, and more especially in discussing each disease, my aim has been to give in a readable form as much information as I could include within a limited space. With that object, my practice has been in every case to read the subject up carefully; to compare the knowledge thus acquired or renewed with the results of my own experience, in those cases in which I had any experience, and then, having taken a more or less definite view of the whole subject, and while my mind was still full of it and of its details, to write as clear and as comprehensive an account as I was capable of. Each article may therefore be regarded as expressing in a condensed form the fulness of my knowledge of its subject at the moment at which it was written. This method of procedure will partly explain both the *ex cathedrâ* tone in which I have, I believe, generally expressed myself, the prevailing absence of notes, quotations, and references to authorities, and perhaps also many inaccuracies and omissions.

I have throughout the work given particular prominence to the pathology and to the clinical phenomena of disease; and in all cases in which the clinical phenomena seem to be the direct consequences of definite lesions (especially therefore in the case of local diseases) my account of the morbid anatomy has been made to precede the clinical description. It may possibly, however, seem to be an

omission that I have only occasionally devoted a special paragraph to the differential diagnosis of diseases. It is so far an omission that I have been driven to it by the exigencies of space. But on the whole I do not regret it; for the distinguishing of one disease from another disease should depend not on the simple recognition of a few leading characters, which however carefully selected are apt not unfrequently to fail us, but on a *bonâ fide* and thorough acquaintance with the collective phenomena of diseases. The more a student is taught to rely on one or two criteria, the less likely is he to investigate diseases intelligently, and the more apt is he to be content with hasty and inaccurate diagnoses.

In respect of the treatment of diseases, again, I may appear to have been in many cases less full and less specific than I ought to have been. The principles by which I have been guided in this matter are easy to explain. In the first place, it seemed to me that works upon the *Materia Medica* are the proper source from which to learn the doses in which medicines may be administered, and the best modes of combining medicines. And in the second place, in considering the details of treatment, as given in most works of medicine, it appeared to me that their authors had for the most part simply recommended those doses of drugs, those combinations of drugs, and those specific modes of administering them, to which they had accustomed themselves. I admit that the subject of my last objection will be regarded by many from quite an opposite point of view. Nevertheless, while, on the one hand, I should hesitate to force my own routine and trivialities of practice upon students, I should equally hesitate to force upon them those of other people. It seems to me best, having inculcated general principles, and pointed out the specific virtues of certain drugs, to leave the young practitioner generally as much unshackled as possible with regard to his choice of particular combinations and modes of administration. He is far more likely to make a thoughtful physician, and, as I think, to benefit his patient, if he adapts his drugs and his methods to the exigencies of cases as they present themselves before him, than if he follows the stereotyped procedure of some predecessor.

From first to last I have carefully avoided quoting illustrative

cases. This course has been forced upon me by the necessity under which I laboured of compressing my work within the narrowest possible limits of space. But it is a course which I adopted reluctantly, and with the full knowledge that I was thereby robbing my pages of much that might have been instructive, of much at any rate that would have rendered them pleasanter reading. Everyone who has perused them knows how much of the charm, the freshness, the vigour, the impressiveness, and the permanent interest, that characterise the classical writings of Abercrombie, of Graves, of Watson, of Trousseau, and of other masters of our art, depend upon the well-told cases with which they are so richly interspersed.

I have already referred to the omission to quote authorities of which I have been generally guilty. The excuses which I have to offer in reference to this matter are mainly the following :—I was anxious to economise space ; I felt, moreover, that my work was not an encyclopædia, still less a history of medicine ; and again, many important additions which have been made to our knowledge, even during the last few years, have already become classical, and form an integral part of the great body of Medical Science. My indebtedness, however, direct or indirect, to innumerable writers and workers I must fully acknowledge ; and among these I must not fail to include my senior colleagues and former teachers of St. Thomas's Hospital, the value of whose teaching to myself I cannot exaggerate. But there are certain works on which I have drawn very largely, and to the authors of which on that account I owe special gratitude : these are, in pathology and morbid anatomy, Rokitsansky's '*Pathological Anatomy*,' Cornil and Ranvier's '*Manual of Pathological Histology*,' and Virchow's writings, including above all his marvellous work on the '*Pathology of Tumours*;' in general medicine Sir T. Watson's '*Lectures on the Principles and Practice of Physic*,' Reynolds's '*System of Medicine*,' Aitken's '*Science and Practice of Medicine*,' Niemeyer's '*Elements of Internal Pathology and Therapeutics*,' and Trousseau's '*Clinical Medicine*'; and in special subjects, Duchenne's admirable work on '*Localised Electrification*,' and the no less admirable Lectures by Charcot on the '*Diseases of the Nervous System*.'

I must apologise for the many omissions, errors, redundancies, and other faults with which I am only too conscious that my work abounds. Fresh from its completion I feel, perhaps not unnaturally, how much better I could do it were I, from the standpoint of my present experience, now to rewrite it. But this is perhaps a delusion. At any rate I can only take credit for what I have done, and not for what I conceive myself capable of doing. The tree must be judged by its fruits.

In conclusion, I beg leave to record my sincere thanks to my friends Drs. H. DONKIN and GREENFIELD for the kind and valuable assistance I have received from them in the progress of this work through the press. They have each read and criticised nearly every page ; and I owe it to them that many mistakes have been corrected, many omissions supplied, and that the reader has been spared the infliction of some grammatical inaccuracies and no little careless spelling.

11 OLD BURLINGTON STREET  
*August 1876.*

# CONTENTS.

## PART I.

	PAGE
GENERAL PATHOLOGY . . . . .	1
I. THE DEFINITION OF DISEASE . . . . .	3
II. THE ÆTIOLOGY OF DISEASE . . . . .	7
A. PREDISPOSING CAUSES OF DISEASE . . . . .	8
1. Age. 2. Sex. 3. Personal Peculiarities. 4. Occupation, habits, &c. 5. Previous disease. 6. Heat and cold, &c. 7. <i>Epidemic constitution. Change of type of disease.</i>	
B. EXCITING CAUSES OF DISEASE . . . . .	13
1. Mechanical. 2. Chemical. 3. Vital—parasites, contagia, malaria, &c.	
III. PHYSIOLOGICAL PROCESSES IN HEALTH . . . . .	18
A. Properties and development of protoplasm. B. Simple tissues—1, <i>epithelial</i> ; 2, <i>connective</i> ; 3, <i>tubular</i> ; 4, <i>organs</i> . C. Development, growth, and maintenance of the organism. Functions, 1, of circulatory system; 2, of digestive system; 3, of excretory system; 4, of nervous system. D. Decay and death essential elements in the processes of life.	
IV. PHYSIOLOGICAL PROCESSES IN DISEASE . . . . .	23
A. MORBID GROWTH . . . . .	24
1. <i>General Observations.</i> . . . .	24
<i>a. Growth and development of cells. b. Conditions associated with overgrowth. c. Migration of leucocytes. d. Tendency of morbid growth to spread locally. e. Tendency of morbid growth to become generalised. f. Tendency of certain morbid growths to limit their distribution to certain tissues or organs. g. Connection of dyscrasia with the origin of morbid growths. h. Secondary dyscrasia. i. Meaning of terms malignant and innocent. k. Relation between infective morbid growths and specific febrile diseases.</i>	
2. <i>Hypertrophy. Hyperplasia</i> . . . . .	32

	PAGE
3. <i>Inflammation</i> . . . . .	34
General account. <i>a.</i> Extra-vascular processes—in cartilage, in mesentery, in cornea, in the vascular tissues. <i>b.</i> Vascular processes. <i>c.</i> <i>Exudation.</i> <i>d.</i> <i>Suppuration.</i> <i>e.</i> Destructive processes—gangrene, ulceration. <i>f.</i> Organisation, granulation, and cicatrization. <i>g.</i> Spread. <i>h.</i> Constitutional effects. <i>i.</i> Varieties. <i>k.</i> Relation of inflammation to septic organisms. Note in reference to recent views as to the nature and processes of inflammation. .	49
4. <i>Tumours</i> . . . . .	50
General account.	
<i>a.</i> <i>Connective-tissue Tumours</i> . . . . .	53
<i>i.</i> <i>Fibrous tumour, or fibroma.</i> <i>ii.</i> <i>Fatty tumour, or lipoma.</i>	
<i>iii.</i> <i>Mucous tumour, or myxoma.</i> <i>iv.</i> <i>Glue-like tumour, or glioma.</i>	
<i>b.</i> <i>Cartilaginous Tumours, or Chondromata</i> . . . . .	55
<i>Ecchondroses; enchondromata.</i>	
<i>c.</i> <i>Osseous Tumours, or Osteomata</i> . . . . .	57
<i>Ivory; compact; spongy. Exostoses. Odontomata.</i>	
<i>d.</i> <i>Nervous Tumours, or Neuromata</i> . . . . .	57
<i>e.</i> <i>Muscular Tumours, or Myomata</i> . . . . .	58
<i>f.</i> <i>Vascular Tumours, or Angiomata</i> . . . . .	59
<i>Simple; cavernous.</i>	
<i>g.</i> <i>Lymphatic Tumours, or Lymphomata</i> . . . . .	59
<i>i.</i> <i>Lymphangioma.</i> <i>ii.</i> <i>Lymphadenoma (lympho-sarcoma);</i> $\alpha$ , simple inflammation; $\beta$ , scrofulous enlargement; $\gamma$ , lymphadenoma.	
<i>h.</i> <i>Sarcomata</i> . . . . .	64
<i>i.</i> <i>Round-cell sarcoma.</i> <i>ii.</i> <i>Spindle-cell sarcoma.</i> <i>iii.</i> <i>Large-cell sarcoma.</i> <i>iv.</i> <i>Melanoid sarcoma.</i> <i>Psammonoma.</i>	
<i>i.</i> <i>Carcinomata, or Cancers</i> . . . . .	67
<i>i.</i> <i>Scirrhus or hard cancer.</i> <i>ii.</i> <i>Encephaloid cancer; erectile or hæmatoid, pultaceous, lipomatous, melanotic.</i> <i>iii.</i> <i>Colloid cancer.</i>	
<i>iv.</i> <i>Epithelioma or canceroid.</i> <i>v.</i> <i>Adenoid or tubular cancer.</i>	
<i>j.</i> <i>Granulomata, or Granulation Tumours</i> . . . . .	74
<i>i.</i> <i>Tubercle: grey or miliary; caseous or yellow. Connection between tubercle and adenoid tissue. Relations between grey and yellow tubercle. Quasi-malignancy of tubercle. Experimental inoculation. Relation of bacilli to tubercle.</i>	
<i>ii.</i> <i>Syphilitic gummata.</i>	
B. ATROPHY, DEGENERATION, AND NECROSIS . . . . .	83
1. <i>Atrophy and Degeneration</i> . . . . .	83
General remarks. <i>a.</i> <i>Cloudy swelling.</i> <i>b.</i> <i>Mucous and colloid degeneration.</i> <i>c.</i> <i>Lardaceous degeneration.</i> <i>d.</i> <i>Fatty degeneration.</i> <i>e.</i> <i>Pigmentary degeneration.</i> <i>f.</i> <i>Uratic degeneration.</i> <i>g.</i> <i>Calcareous degeneration.</i>	
2. <i>Necrosis, or Gangrene</i> . . . . .	91

	PAGE
C. MECHANICAL AND FUNCTIONAL DERANGEMENTS . . . . .	94
1. <i>Mechanical Derangements</i> . . . . .	94
<i>a.</i> Displacement of parts. <i>b.</i> Compression, contraction, and impaction. <i>c.</i> Dilatation: <i>Cysts.</i> i. Cysts by dilatation of natural cavities; ii. cysts by distension of ducts or retention; iii. cysts by extravasation; iv. cysts by softening of tissues. <i>d.</i> Rupture and extravasation.	
2. <i>Functional Derangements</i> . . . . .	98
<i>a. Congestion</i> . . . . .	99
i. Active. ii. Passive.	
<i>b. Dropsy</i> . . . . .	100
i. General. ii. Local.	
<i>c. Fever</i> . . . . .	103
i. Normal temperature. Conditions which determine and re- gulate heat of body. ii. Febrile temperature. <i>Hyperpyrexia.</i> Symptoms attending febrile temperature. Condition of skin; of circulation; of respiration; of digestive organs; of urine; of nervous system. Causes of death in fever. Causes of febrile temperature. iii. <i>Hectic fever.</i> iv. <i>The thermometer.</i>	
<i>d. The Typhoid Condition</i> . . . . .	113
Symptoms. Causes.	
<i>e. Collapse. Syncope.</i> . . . . .	115
Symptoms of collapse. Symptoms of syncope. Depression of temperature. Feebleness of circulation. Condition of nervous functions.	
<i>f. Death</i> . . . . .	117
i. From failure of nutrition. ii. From failure of the circula- tion. iii. From failure of the elimination of effete and poisonous matters. iv. From failure of the nervous system to perform its proper functions.	
V. THE TREATMENT OF DISEASE . . . . .	122
<i>A. Hygienic Treatment.</i> . . . . .	122
<i>B. Prophylactic Treatment</i> . . . . .	123
1. Prophylaxis in relation to the tendency, inherited or acquired, to disease. 2. Prophylaxis in relation to parasitic, endemic, and infectious diseases. 3. Prophylaxis in relation to the compli- cations or sequelæ of disease.	
<i>C. Remedial and Therapeutical Treatment</i> . . . . .	124
1. To render the patient's condition as comfortable as circum- stances permit. 2. The maintenance of the patient's strength. 3. The maintenance or improvement of the nutritive functions. 4. The elimination of effete matters. 5. The treatment of symptoms. 6. The obviation of the tendency to death.

Causation and description. Treatment.	
XXXI. ATROPHY (A. <i>Glossy Skin</i> . B. <i>Linear Atrophy</i> .) C. Treatment	362
XXXII. PRURIGO . . . . .	363
Description. Treatment.	
XXXIII. CONCLUDING REMARKS . . . . .	364

CHAP. III.—DISEASES OF THE RESPIRATORY ORGANS . . . .	365
I. INTRODUCTORY REMARKS . . . . .	365
A. <i>Anatomical Relations</i> . . . . .	365
1. Organs of Respiration. 2. Regions of chest.	
B. <i>Pathology of Voice, Respiration, Cough, and Expectoration</i> . .	367
1. Voice : feebleness, absence, pitch, quality. 2. Respiration : frequency, dyspnœa. 3. Cough : varieties. 4. Expectoration : varieties.	
C. <i>Investigation by Sight and Touch</i> . . . . .	373
1. Larynx and trachea. <i>Laryngoscope</i> . 2. Chest : form, movements, fremitus. <i>Spirometer</i> .	
D. <i>Investigation by Percussion and Auscultation</i> . . . . .	378
1. PERCUSSION . . . . .	378
a. Normal percussion phenomena : i. <i>Resonance</i> ; ii. <i>Dulness</i> . b. Abnormal percussion phenomena : i. <i>Dulness</i> ; ii. <i>Resonance</i> . c. <i>Resistance</i> .	
2. AUSCULTATION . . . . .	383
The <i>stethoscope</i> . a. Normal auscultatory phenomena : i. Auscultation of the breath ; ii. Auscultation of the voice. b. Abnormal	

auscultatory phenomena: i. *Tubular* or *bronchial* breathing; ii. *Amphoric, cavernous, or metallic* breathing; iii. *Bronchophony, pectoriloquy, and ægophony*; iv. *Crepitation, rales*; v. *Rhonchus*; vi. *Splashing*; vii. *Amphoric bubble*; viii. *Friction sounds*.

E. *Detection of Cavities, Consolidated Lung, and Pleural Effusion* 395

II. LARYNGITIS AND TRACHEITIS . . . . . 396

Causation. Morbid anatomy. Symptoms and progress; 1. *Acute laryngitis*; 2. *Chronic laryngitis*; *aphonia clericorum*; *tubercular and syphilitic laryngitis*. 3. *Tracheitis*. Treatment.

III. BRONCHITIS . . . . . 403

Causation. Morbid anatomy. Symptoms and progress. 1. *Acute bronchitis*; 2. *Chronic bronchitis*. Treatment.

IV. PNEUMONIA . . . . . 410

Causation. Morbid anatomy: A. *Lobar pneumonia*; engorgement, red and grey hepatisation; B. *Lobular pneumonia*. Symptoms and progress. Treatment.

V. PLEURISY (*Pleuritis*) . . . . . 420

Causation. Morbid anatomy: effusion; suppuration (*empyema*); consequences. Symptoms and progress. Treatment.

VI. CIRRHOSIS (*Chronic Pneumonia. Fibroid Phthisis*) . . . . 430

Definition. Causation. Morbid anatomy. Symptoms. Treatment.

VII. TUBERCLE (*Laryngeal and Pulmonary Phthisis. Tubercular Pleurisy*) . . . . . 435

Causation. Morbid anatomy: 1. *Laryngeal tubercle*; 2. *Pulmonary tubercle*; 3. *Pleural tubercle*. Symptoms and progress: chronic; acute. Treatment.

VIII. SYPHILIS . . . . . 450

Morbid anatomy: 1. *Larynx, trachea, and bronchial tubes*; 2. *Lungs*. Symptoms and progress. Treatment.

IX. TUMOURS . . . . . 452

A. *Tumours of Larynx* . . . . . 452

Morbid anatomy: 1. *Non-malignant tumours*; 2. *Malignant tumours*. Symptoms and progress. Treatment.

B. *Tumours of Lungs and Pleuræ* . . . . . 453

Morbid anatomy: 1. *Non-malignant tumours*; 2. *Malignant tumours*. Symptoms and progress. Treatment.

X. PARASITES. HYDATIDS . . . . . 457

Morbid anatomy. *Hydatids*. Symptoms and progress. Treatment.

XI. BRONCHIECTASIS (*Dilatation of Bronchial Tubes*) . . . . 458

Causation and morbid anatomy. Varieties. Symptoms and progress. Treatment.

	PAGE.
XII. EMPHYSEMA . . . . .	461
Causation and morbid anatomy. 1. <i>Interlobular</i> . 2. <i>Vesicular</i> . Varieties of vesicular. Symptoms and progress. Treatment.	
XIII. CONGESTION . . . . .	466
Causation and morbid anatomy. 1. Congestion of larynx, trachea, and bronchial tubes. 2. Congestion of lungs. Symptoms. Treatment.	
XIV. DROPSY. HYDROTHORAX. . . . .	467
Causation and morbid anatomy. 1. <i>Œdema of Larynx</i> . 2. <i>Œdema of Lungs</i> . 3. <i>Pleural dropsy</i> , or <i>Hydrothorax</i> . Symptoms. Treatment.	
XV. PULMONARY COLLAPSE. ATELECTASIS . . . . .	469
Causation and morbid anatomy. Varieties. Symptoms and progress. Treatment.	
XVI. HEMORRHAGE. PULMONARY APOPLEXY. HÆMOPTYSIS . . . . .	471
Causation and morbid anatomy. Varieties. Symptoms and progress. Treatment.	
XVII. PNEUMOTHORAX . . . . .	474
Causation and morbid anatomy. Symptoms and progress. Treatment.	
XVIII. PARALYTIC AFFECTIONS OF THE LARYNX . . . . .	475
1. Paralysis of the superior laryngeals: <i>a</i> . Bilateral; <i>b</i> . Uni- lateral. 2. Paralysis of the recurrent laryngeals: <i>a</i> . Bilateral; <i>b</i> . Unilateral. 3. Paralysis of the pneumogastric. 4. Paralysis of one or both of the posterior crico-arytenoidei. 5. Paralysis of the lateral crico-arytenoidei (adductors). 6. Paralysis of the ary- tenoideus. 7. Paralysis of the thyro-arytenoidei. Treatment.	
XIX. SPASM OF THE LARYNX AND TRACHEA . . . . .	478
1. Larynx. 2. Trachea. Treatment.	
XX. ASTHMA ( <i>Spasm of the Bronchial Tubes</i> ) . . . . .	479
Definition. Causation. Symptoms and progress. Pathology. Treatment.	
XXI. HAY-ASTHMA ( <i>Hay-Fever</i> ) . . . . .	483
Definition. Causation. Symptoms and progress. Treatment.	
<hr/>	
CHAP. IV.—DISEASES OF THE VASCULAR ORGANS . . . . .	485
SECTION I.—DISEASES OF THE HEART . . . . .	485
I. INTRODUCTORY REMARKS . . . . .	485
A. <i>Anatomy and Anatomical Relations of the Heart</i> . . . . .	485
1. Dimensions of heart. 2. Relations of heart to pericardium. 3. Relations of heart to chest-walls and surrounding organs.	

	PAGE.
B. <i>Physiology of the Heart</i> . . . . .	488
1. Action of heart. 2. Sounds of heart. 3. Pulse: Varieties.	
C. <i>Pathology of the Heart</i> . . . . .	493
1. <i>Physical Examination</i> . . . . .	493
a. Inspection. b. Palpation. c. Percussion. d. Auscultation.	
2. <i>Displacement of the Heart</i> . . . . .	495
3. <i>Affections of Pericardium</i> . . . . .	495
a. Pericardial effusion. b. Pericardial roughness and friction.	
c. Pericardial adhesions and growths.	
4. <i>Affections of the Muscular Walls and Cavities</i> . . . . .	497
a. Atrophy. b. Hypertrophy and dilatation. c. Signs and symptoms of atrophy. d. Signs and symptoms of hypertrophy and dilatation.	
5. <i>Affections of the Valves</i> . . . . .	500
a. Causes of valve-disease. b. Manner of valve-disease. c. Effects of valve-disease on walls and cavities of heart. d. Cardiac murmurs. e. Differential diagnosis of cardiac murmurs: i. <i>Aortic valve disease</i> ; ii. <i>Pulmonic valve disease</i> ; iii. <i>Mitral valve disease</i> ; iv. <i>Tricuspid valve disease</i> ; v. <i>Multiple valve disease</i> . f. Other physical signs. g. Effects of valve-disease on general organism: i. Venous pulsation; ii. Hepatic pulsation; iii. Clubbing of fingers.	
6. <i>Inorganic or Hæmic Murmurs in Heart and Murmurs in Vessels</i> . . . . .	510
a. From palpitation. b. Hæmic murmurs. c. From action of heart on lungs. d. Arterial murmurs. e. Venous murmurs. f. Arterio-venous murmurs.	
7. <i>Motor and Sensory Derangements</i> . . . . .	514
a. Motor derangements: asynchronism. b. Abnormal sensations.	
8. <i>Prognosis of Cardiac Derangements</i> . . . . .	517
9. <i>Treatment of Cardiac Derangements</i> . . . . .	519
II. PERICARDITIS, MYOCARDITIS, AND ENDOCARDITIS . . . . .	521
A. <i>Pericarditis</i> . . . . .	521
Causation. Morbid anatomy. Symptoms and progress.	
B. <i>Myocarditis</i> . . . . .	526
Causation. Morbid anatomy. Symptoms and progress.	
C. <i>Endocarditis</i> . . . . .	527
Causation. Morbid anatomy. Symptoms and progress.	
D. <i>Treatment</i> . . . . .	530
III. MORBID GROWTHS AND PARASITES . . . . .	531
A. <i>Fatty growth</i> . B. <i>Tubercle</i> . C. <i>Syphilis</i> . D. <i>Malignant Disease</i> . E. <i>Parasites</i> . F. <i>Treatment</i> .	

	PAGE
IV. DEGENERATIONS . . . . .	534
A. <i>Degenerations of the Muscular Walls</i> . . . . .	534
Causation and morbid anatomy. 1. <i>Fatty degeneration</i> . 2. <i>Granular degeneration</i> . 3. <i>Fibroid degeneration</i> . Symptoms.	
B. <i>Degenerations of the Valves and Endocardium</i> . . . . .	535
Causation and morbid anatomy. Symptoms.	
C. <i>Degenerations of the Coronary Arteries</i> . . . . .	537
D. <i>Treatment</i> . . . . .	537
V. ANEURYSM OF THE HEART . . . . .	537
Causation. Morbid anatomy. Symptoms.	
VI. RUPTURE OF THE HEART. EFFUSION OF BLOOD INTO PERICARDIUM	539
Causation. Morbid anatomy. Symptoms and progress. Other ruptures of the heart.	
VII. HYDRO-PERICARDIUM . . . . .	540
VIII. SYNCOPE . . . . .	541
Causation. Treatment.	
IX. PALPITATION. RECURRENT PALPITATION . . . . .	542
A. <i>Palpitation</i> . . . . .	542
B. <i>Recurrent Palpitation</i> . . . . .	542
Definition. Causation. Symptoms and progress. Pathology. Treatment.	
X. CARDIAC NEURALGIA. ANGINA PECTORIS . . . . .	544
Causation. Pathology. Symptoms and progress. Treatment.	
XI. CYANOSIS AND MALFORMATIONS . . . . .	546
A. <i>Cyanosis</i> . . . . .	546
Causation. Symptoms and progress. Pathology.	
B. <i>Malformations</i> . . . . .	548
Causation and morbid anatomy. Symptoms and progress.	
C. <i>Treatment</i> . . . . .	549
SECTION II.—DISEASES OF THE ARTERIES . . . . .	549
I. ARTERITIS . . . . .	549
A. <i>Periarteritis</i> . Causation and morbid anatomy. Symptoms.	
B. <i>Endoarteritis</i> . Causation and morbid anatomy. Symptoms.	
II. DEGENERATION OF ARTERIES . . . . .	552
Causation and morbid anatomy. Symptoms.	
III. ANEURYSM ( <i>Dilatation of Arteries</i> ) . . . . .	553
Definition. Causation. Morbid anatomy. Effects of aneurysms on neighbouring parts; results. Symptoms and progress. Treatment.	

	PAGE
A. <i>Thoracic Aneurysms</i> . . . . .	559
Morbid anatomy and symptoms. 1. Impediment to arterial circulation. 2. Impediment to venous circulation. 3. Pressure on nerves. 4. Pressure on trachea and bronchial tubes. 5. Pressure on œsophagus. Treatment.	
B. <i>Abdominal Aneurysms</i> . . . . .	564
Morbid anatomy and symptoms. Treatment.	
SECTION III.—DISEASES OF THE VEINS . . . . .	565
I. PHLEBITIS . . . . .	565
Causation and morbid anatomy. Symptoms.	
II. VARIX ( <i>Dilatation of the Veins</i> ) . . . . .	566
Causation. Morbid anatomy.	
SECTION IV.—ARTERIAL AND VENOUS OBSTRUCTIONS . . . . .	567
THROMBOSIS AND EMBOLISM . . . . .	567
Definition.	
A. <i>Thrombosis</i> . . . . .	567
Causation. Morbid anatomy. 1. In heart. 2. In veins. 3. In arteries.	
B. <i>Embolism</i> . . . . .	570
Causation and morbid anatomy.	
C. <i>Consequences and Symptoms of Thrombosis and Embolism</i> . . . . .	571
1. <i>Phlegmasia alba dolens</i> . Treatment. 2. <i>Cardiac thrombosis</i> . 3. <i>Embolism and thrombosis of the pulmonary artery</i> . 4. <i>Embolism and thrombosis of the larger systemic arteries</i> . Treatment. 5. <i>Multiple embolism of the smaller systemic arteries—ulcerative endocarditis</i> . Treatment.	
SECTION V.—DISEASES OF THE DUCTLESS GLANDS, BLOOD, &c. . . . .	576
I. GRAVES'S DISEASE ( <i>Exophthalmic Goitre</i> ). . . . .	576
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
II. DISEASES OF THE THYROID BODY . . . . .	579
A. <i>Goitre (Bronchocœle)</i> . . . . .	579
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
B. <i>Cretinism</i> . . . . .	584
Treatment.	
III. MYXŒDEMA . . . . .	586
Definition and history. Causation. Symptoms and progress. Morbid anatomy. Treatment.	
IV. DISEASES OF THE SUPRA-RENAL CAPSULES. . . . .	588
A. <i>Addison's Disease (Melasma Addisonii)</i> . . . . .	588
Definition. Causation. Morbid anatomy and pathology. Symptoms and progress. Treatment.	
B. <i>Tumours of the Supra-renal Capsules</i> . . . . .	592

	PAGE
V. DISEASES OF THE SPLEEN . . . . .	592
A. <i>Congestion</i> . . . . .	592
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
B. <i>Hypertrophy</i> . . . . .	593
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
C. <i>Inflammation</i> . . . . .	594
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
D. <i>Tubercle</i> . . . . .	595
E. <i>Tumours</i> . . . . .	596
F. <i>Cysts and Hydatids</i> . . . . .	596
G. <i>Atrophy</i> . . . . .	597
H. <i>Lardaceous Degeneration</i> . . . . .	597
Morbid anatomy. Symptoms. Treatment.	
VI. DISEASES OF THE LYMPHATICS . . . . .	598
A. <i>Inflammation</i> . . . . .	598
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
B. <i>Tubercle. Scrofula</i> . . . . .	599
Morbid anatomy. Symptoms and progress. Treatment.	
C. <i>Morbid Growths</i> . . . . .	600
Morbid anatomy. Symptoms and progress. Treatment.	
D. <i>Mediastinal Tumours</i> . . . . .	600
Morbid anatomy. Symptoms and progress. Treatment.	
E. <i>Obstruction and Dilatation of Lymphatics</i> . . . . .	602
Morbid anatomy. Symptoms and progress. Treatment.	
I. LEUCOCYTHÆMIA ( <i>Leukæmia</i> ) . . . . .	604
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
VIII. IDIOPATHIC ANÆMIA ( <i>Chlorosis. Pernicious anæmia</i> ) . . . . .	607
Definition. Causation. Symptoms and progress: <i>Chlorosis</i> ; <i>Pernicious anæmia</i> . Morbid anatomy and pathology. Treatment.	
IX. HÆMOPHILIA ( <i>Hemorrhagic diathesis</i> ) . . . . .	612
Definition. Causation. Symptoms and progress. Treatment.	
X. PURPURA . . . . .	613
Definition. Causation. Symptoms and progress. Varieties. Morbid anatomy. Treatment.	
XI. RAYNAUD'S DISEASE . . . . .	616
Definition and history. Causation and morbid anatomy. Varieties. Treatment.	

	PAGE
XII. SCURVY ( <i>Scorbutus</i> ) . . . . .	620
Definition. Causation. Symptoms and progress. Morbid anatomy. Treatment.	
XIII. CHRONIC ALCOHOLIC POISONING ( <i>Alcoholism</i> ). DELIRIUM TREMENS	622
<i>Nervous Disorders. Delirium Tremens</i> . . . . .	623
Causation. Symptoms. Pathology and morbid anatomy. Treatment.	
XIV. CHRONIC LEAD-POISONING ( <i>Plumbism</i> ). COLIC. DROPPED HAND .	627
Causation. Symptoms and progress. A. <i>Lead Colic</i> . B. <i>Nervous disorders. Dropped hand</i> . Pathology and morbid anatomy. Treatment.	
XV. CHRONIC MERCURIAL POISONING ( <i>Mercurialism</i> ) . . . . .	633
Causation. Symptoms and progress. Morbid anatomy. Treatment.	
<hr/>	
CHAP. V.—DISEASES OF THE DIGESTIVE ORGANS .	636
SECTION I.—DISEASES OF THE MOUTH, FAUCES, AND ADJACENT PARTS .	636
I. CATARRH . . . . .	636
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
II. THRUSH ( <i>Aphthæ</i> ) . . . . .	639
Causation and morbid anatomy. <i>Oidium albicans</i> . Symptoms and progress. Treatment.	
III. STOMATITIS . . . . .	641
A. <i>Simple Ulcerative Stomatitis</i> . . . . .	641
Causation. Symptoms and progress. Treatment.	
B. <i>Acute Ulcerative Stomatitis</i> . . . . .	642
Causation and morbid anatomy. Symptoms and progress. Treatment.	
IV. NOMA ( <i>Gangrenous Stomatitis</i> ). GANGRENE OF FAUCES . .	643
A. <i>Noma</i> . Causation. Morbid anatomy. Symptoms and progress. B. <i>Gangrene of fauces</i> . Causation. Symptoms and progress. C. Treatment.	
V. INFLAMMATION OF THE GUMS IN DENTITION . . . . .	645
VI. GLOSSITIS . . . . .	646
Causation. Symptoms and progress. Treatment.	
VII. GRANULAR PHARYNGITIS . . . . .	647
Definition. Causation. Symptoms and progress. Treatment.	
VIII. QUINSY ( <i>Tonsillitis</i> ) . . . . .	648
A. <i>Acute Tonsillitis</i> . . . . .	648
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
B. <i>Chronic Tonsillitis</i> . . . . .	651
Symptoms and progress. Treatment.	

	PAGE
IX. RETRO-PHARYNGEAL ABSCESS . . . . .	651
Causation. Symptoms and progress. Treatment.	
X. 'DRY MOUTH' . . . . .	652
XI. OZÆNA . . . . .	652
Causation. Symptoms. Treatment.	
XII. MORBID GROWTHS . . . . .	653
A. <i>Tubercle.</i> B. <i>Syphilis.</i> C. <i>Malignant tumours.</i> Treat- ment.	
SECTION II.—DISEASES OF THE ŒSOPHAGUS . . . . .	655
I. INTRODUCTORY REMARKS . . . . .	655
<i>Anatomical Relations</i> . . . . .	655
II. INFLAMMATION OF THE ŒSOPHAGUS . . . . .	655
Causation and morbid anatomy. Symptoms.	
III. CHRONIC AND OBSTRUCTIVE DISEASES OF THE ŒSOPHAGUS . . . . .	656
A. <i>Ulceration</i> . . . . .	656
Causation and morbid anatomy.	
B. <i>Morbid Growths</i> . . . . .	656
Morbid anatomy.	
C. <i>Affections implicating the Œsophagus from without</i> . . . . .	657
Causation and morbid anatomy.	
D. <i>Dilatation</i> . . . . .	657
Causation and morbid anatomy.	
E. <i>Spasm and Paralysis</i> . . . . .	658
F. <i>Symptoms. Dysphagia</i> . . . . .	658
G. <i>Treatment</i> . . . . .	661
SECTION III.—DISEASES OF STOMACH, INTESTINES, AND PERITONEUM . . . . .	662
I. INTRODUCTORY REMARKS . . . . .	662
A. <i>Anatomical Relations</i> . . . . .	662
B. <i>Examination of the Abdomen</i> . . . . .	663
1. Inspection. 2. Palpation. 3. Percussion. 4. Auscultation.	
II. GASTRITIS . . . . .	666
Causation. Morbid anatomy. Symptoms and progress. Va- rieties. Treatment.	
III. ENTERITIS . . . . .	671
Causation. Morbid anatomy. Symptoms and progress. Va- rieties. Treatment.	
IV. ULCERATION OF THE STOMACH . . . . .	676
Causation. Morbid anatomy. Symptoms and progress. Treat- ment.	
V. ULCERATION OF THE BOWELS . . . . .	680
Causation and morbid anatomy. Varieties of ulcer. Symptoms and progress. Treatment.	

	PAGE.
VI. PERFORATING ULCERS OF THE CÆCUM AND RECTUM . . . . .	685
A. <i>Typhlitis, Perityphlitis</i> . . . . .	686
Causation and morbid anatomy. Symptoms and progress.	
Treatment.	
B. <i>Periproctitis</i> . . . . .	688
Causation and morbid anatomy. Symptoms and progress.	
Treatment.	
VII. DYSENTERY . . . . .	689
Definition. Causation. Morbid anatomy. Symptoms and progress.	
Treatment.	
VIII. PERITONITIS . . . . .	696
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
IX. CIRRHOSIS OF THE STOMACH AND BOWELS . . . . .	703
Morbid anatomy. Symptoms.	
X. TUBERCLE ( <i>Abdominal Phthisis</i> ) . . . . .	704
Morbid anatomy. 1. Bowels. 2. Peritoneum and abdominal	
lymphatic glands. Symptoms and progress. 1. Bowels. 2. Peri-	
toneum. Treatment.	
XI. TUMOURS . . . . .	708
A. <i>Non-Malignant Tumours</i> . . . . .	708
<i>Polypi, villous growths.</i>	
B. <i>Malignant Tumours</i> . . . . .	709
Morbid anatomy. 1. <i>Scirrhus cancer.</i> 2. <i>Colloid.</i> 3. <i>Ence-</i>	
<i>phaloid.</i> 4. <i>Epithelioma.</i> 5. <i>Adenoid cancer.</i> 6. <i>Sarcoma and</i>	
<i>lymphadenoma.</i> Symptoms and progress. 1. Stomach. 2. Bowels.	
3. Peritoneum and glands. Treatment.	
XII. ANIMAL PARASITIC AFFECTIONS . . . . .	717
A. <i>Tape-Worms and Cyst-Worms (Cestoda or Tæniada)</i> . . . . .	717
1. General account . . . . .	717
2. <i>Tænia Solium, Tænia Mediocanellata, and Bothriocephalus Latus</i>	718
Symptoms. Treatment.	
3. <i>Tænia Echinococcus. Hydatid</i> . . . . .	722
B. <i>Round-Worms (Nematoda)</i> . . . . .	725
1. General account . . . . .	725
2. <i>Common Round-Worm (Ascaris Lumbricoides)</i> . . . . .	725
Symptoms. Treatment.	
3. <i>Common Thread-Worm or Seat-Worm (Oxyuris Vermicularis)</i> .	727
Symptoms. Treatment.	
4. <i>Whip-Worm (Trichocephalus Dispar)</i> . . . . .	727
5. <i>Dochmius Duodenalis (Sclerostoma Duodenale)</i> . . . . .	728

	PAGE
6. <i>Trichina Spiralis. Trichinosis</i> . . . . .	729
Symptoms and progress. Treatment.	
7. <i>Filaria Sanguinis Hominis</i> . . . . .	732
XIII. VEGETABLE PARASITIC AFFECTIONS . . . . .	735
A. <i>Actinomycosis</i> . . . . .	735
History and morbid anatomy. Symptoms and progress.	
Treatment.	
B. <i>Mycetoma (Fungus Disease of India. Madura Foot)</i> . . . . .	737
History and morbid anatomy. Symptoms and progress.	
XIV. DEGENERATIVE AFFECTIONS OF THE STOMACH AND BOWELS . . . . .	738
XV. OBSTRUCTION OF THE STOMACH . . . . .	738
Causation and morbid anatomy. Symptoms and progress.	
Treatment.	
XVI. OBSTRUCTION OF THE BOWELS . . . . .	741
A. <i>Constipation</i> . . . . .	741
Causation, morbid anatomy, and symptoms.	
B. <i>Stricture</i> . . . . .	742
Causation and morbid anatomy. Symptoms and progress.	
C. <i>Compression and Traction</i> . . . . .	745
Causation and morbid anatomy. Symptoms and progress.	
D. <i>Torsion or Twisting</i> . . . . .	746
Causation and morbid anatomy. Symptoms and progress.	
E. <i>Internal Strangulation</i> . . . . .	747
Causation and morbid anatomy. Symptoms.	
F. <i>Impaction of Foreign Bodies</i> . . . . .	748
Causation and morbid anatomy. Symptoms and progress.	
G. <i>Intussusception</i> . . . . .	749
Causation and morbid anatomy. Symptoms and progress.	
H. <i>Concluding Remarks in reference to Symptoms of Obstruction</i> . . . . .	753
1. Pain. 2. Vomiting. 3. Constipation. 4. Tumour and shape	
of belly. 5. Condition of urine. 6. Duration of life. 7. Statistics.	
I. <i>Treatment</i> . . . . .	755
XVII. ASCITES ( <i>Abdominal Dropsy</i> ). . . . .	758
Causation and morbid anatomy. Symptoms and progress.	
Treatment.	
XVIII. HEMORRHAGE. HÆMATEMESIS. MELÆNA . . . . .	762
Definition. Causation. Symptoms and progress. Treatment.	
XIX. DYSPEPSIA ( <i>Indigestion</i> ). . . . .	764
Definition. Causation. 1. Symptoms referrible to the stomach :	
appetite ; abnormal sensations ; flatulence and eructation ; nausea	
and sickness ; pyrosis. 2. Symptoms referrible to other organs.	
Treatment.	

	PAGE
XX. DIARRHŒA . . . . .	773
Causation. Symptoms and progress. Treatment. Raw meat in treatment.	
SECTION IV.—DISEASES OF THE LIVER AND PANCREAS . .	779
I. INTRODUCTORY REMARKS . . . . .	779
A. <i>Anatomical Relations</i> . . . . .	779
B. <i>Physiological Considerations</i> . . . . .	780
C. <i>Pathological Considerations</i> . . . . .	781
<i>Jaundice.</i>	
II. INFLAMMATION OF THE HEPATIC DUCTS . . . . .	785
Causation. Morbid anatomy. Symptoms and progress. Treat- ment.	
III. ACUTE HEPATITIS. ABSCESS OF THE LIVER . . . . .	787
Causation. Morbid anatomy. Symptoms and progress. Treat- ment.	
IV. CIRRHOSIS OF THE LIVER . . . . .	792
A. <i>Atrophic Cirrhosis (Hobnailed or Drunkard's Liver)</i> . .	792
Causation. Morbid anatomy. Symptoms and progress.	
B. <i>Hypertrophic Cirrhosis</i> . . . . .	794
Causation and morbid anatomy. Symptoms and progress.	
C. <i>Other conditions allied to Cirrhosis</i> . . . . .	795
Causation and morbid anatomy. 1. <i>Syphilitic cirrhosis.</i> 2. <i>Syphilitic contraction.</i> 3. <i>Perihepatitis.</i> Symptoms and pro- gress.	
D. <i>Treatment of Cirrhosis</i> . . . . .	796
V. CONGESTION OF THE LIVER ( <i>Nutmeg Liver</i> ) . . . . .	797
Causation. Morbid anatomy. Symptoms and progress. Treat- ment.	
VI. MORBID GROWTHS . . . . .	798
A. <i>Tubercle</i> . . . . .	798
B. <i>Syphilis</i> . . . . .	799
Morbid anatomy. Symptoms. Treatment.	
C. <i>Non-Malignant Growths</i> . . . . .	800
D. <i>Malignant Growths</i> . . . . .	801
Morbid anatomy. Symptoms and progress. Treatment.

XI. OBSTRUCTION OF THE HEPATIC DUCTS . . . . .	817
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
XII. JAUNDICE WITHOUT OBVIOUS OBSTRUCTION OF DUCTS . . . . .	821
Causation. Morbid anatomy. Symptoms. Treatment.	
XIII. MALIGNANT JAUNDICE ( <i>Yellow Atrophy of the Liver</i> ) . . . . .	822
Definition. Causation. Symptoms and progress. Morbid anatomy. Treatment.	
XIV. DISEASES OF THE PANCREAS . . . . .	825
A. <i>Introductory Remarks</i> . . . . .	825
B. <i>Hyperæmia and Inflammation</i> . . . . .	825
C. <i>Morbid Growths</i> . . . . .	826
D. <i>Calculi</i> . . . . .	826
E. <i>Obstruction of the Pancreatic Ducts</i> . . . . .	826
F. <i>Symptoms and Treatment</i> . . . . .	826
<hr/>	
CHAP. VI.—DISEASES OF THE GENITO-URINARY ORGANS	827
SECTION I.—DISEASES OF THE KIDNEYS . . . . .	827
I. INTRODUCTORY REMARKS . . . . .	827
<i>General Physiological and Pathological Considerations</i> . . . . .	827
A. <i>Characters and Composition of the Urine</i> . . . . .	828
1. Physical characters of morbid urine. 2. <i>Urea</i> . 3. <i>Uric acid and urates</i> . 4. <i>Xanthine</i> . 5. <i>Cystine</i> . 6. <i>Leucine, and tyrosine</i> . 7. <i>Colouring matters</i> . 8. <i>Odorous matters</i> . <i>Grape sugar</i> . 10. <i>Amorphous phosphate of lime</i> . 11. <i>Crystallised phosphate</i> . 12. <i>Ammoniac-magnesian phosphate</i> . 13. <i>Oxalate of lime</i> . 14. <i>Carbonate of lime</i> . 15. <i>Albumen</i> . 16. <i>Blood</i> . 17. <i>Bile</i> . 18. <i>Casts</i> . 19. <i>Mucus and pus</i> . 20. <i>Fat</i> . 21. <i>Morbid growths</i> . 22. <i>Spermatozoa</i> . 23. <i>Animal and vegetable organisms</i> .	
B. <i>Concretions</i> . . . . .	846
1. <i>Uric acid</i> . 2. <i>Uratic</i> . 3. <i>Cystine</i> . 4. <i>Xanthine</i> . 5. <i>Oxalate of lime</i> . 6. <i>Amorphous phosphate and ammoniac-magnesian phosphate</i> . 7. <i>Carbonate of lime</i> . <i>Blood, indigo, &amp;c.</i>	
C. <i>The specific consequences of the Retention of Urea and other matters in the blood</i> . . . . .	847
1. Thickening and contraction of the smaller blood-vessels. 2. Hypertrophy of the heart. 3. Anasarca and other dropsical effusions. 4. Congestion and hemorrhages. 5. Inflammatory affections. 6. Functional consequences.	
D. <i>The Non-specific Morbid Phenomena which attend on and characterise Lesions of the Kidneys</i> . . . . .	850

	PAGE
II. PYELITIS . . . . .	851
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
III. CIRCUMSCRIBED AND SUPPURATIVE NEPHRITIS . . . . .	854
Causation. Morbid anatomy. Symptoms. Treatment.	
IV. ACUTE BRIGHT'S DISEASE ( <i>Acute Albuminous, Desquamative, or Tubal Nephritis</i> ) . . . . .	855
Causation. Morbid anatomy. Varieties. Symptoms and progress. Treatment.	
V. CHRONIC BRIGHT'S DISEASE . . . . .	859
A. <i>Chronic Parenchymatous or Tubal Nephritis (Large White Kidney and Fatty Kidney)</i> . . . . .	859
Causation. Morbid anatomy. Symptoms and progress.	
B. <i>Chronic Interstitial Nephritis (Contracted Granular Kidney. Gouty Kidney)</i> . . . . .	862
Causation. Morbid anatomy. The cystic kidney. Symptoms and progress.	
C. <i>Treatment of Chronic Bright's Disease</i> . . . . .	866
VI. CONGESTION OF THE KIDNEY . . . . .	867
Causation. Morbid anatomy. Symptoms. Treatment.	
VII. TUBERCULAR DISEASE OF THE KIDNEY . . . . .	868
Morbid anatomy. Symptoms and progress. Treatment.	
VIII. SYPHILITIC DISEASE OF THE KIDNEY . . . . .	869
IX. MORBID GROWTHS OF THE KIDNEY . . . . .	870
Morbid anatomy. 1. <i>Lymphadenoma</i> . 2. <i>Sarcoma</i> . 3. <i>Carcinoma</i> . Symptoms and progress. Treatment.	
X. PARASITIC AFFECTIONS OF THE KIDNEY . . . . .	872
A. <i>Hydatid cysts</i> . Treatment. B. <i>Bilharzia hæmatobia</i> . Treatment.	
XI. LARDACEOUS DEGENERATION OF THE KIDNEY . . . . .	873
Causation. Morbid anatomy. Symptoms and progress. Treatment.	
XII. GRAVEL AND RENAL CALCULI . . . . .	874
Causation and morbid anatomy. Symptoms and progress. Treatment.	
XIII. HYDRO-NEPHROSIS AND ATROPHY OF THE KIDNEY . . . . .	878
Causation and morbid anatomy. Symptoms and progress. Treatment.	
XIV. MISPLACED AND MOVABLE OR FLOATING KIDNEY . . . . .	879
Causation and morbid anatomy. Symptoms. Treatment.	

	PAGE
XV. CHYLURIA ( <i>Chylous Urine</i> ) . . . . .	880
Causation and symptoms. Pathology. Treatment.	
XVI. HÆMATURIA . . . . .	882
Causation and symptoms. Treatment.	
XVII. PAROXYSMAL HÆMOGLOBINURIA ( <i>Paroxysmal Hæmatinuria and Hæmaturia</i> ) . . . . .	883
Definition. Causation. Symptoms and progress. Pathology. Treatment.	
XVIII. DIABETES ( <i>Diabetes Mellitus. Glycosuria</i> ) . . . . .	886
Definition. Causation. Symptoms and progress. Morbid anatomy and pathology. Treatment.	
XIX. DIABETES INSIPIDUS ( <i>Diuresis</i> ) . . . . .	892
Causation. Symptoms and progress. Morbid anatomy. Treatment.	
XX. SUPPRESSION OF URINE ( <i>Ischuria Renalis</i> ) . . . . .	894
A. Functional suppression of urine. B. Suppression of urine from obstruction. Symptoms and progress. Treatment.	
SECTION II.—DISEASES OF THE PELVIC ORGANS . . . . .	895
I. DISEASES OF THE URINARY BLADDER . . . . .	896
1. <i>Inflammation</i> . . . . .	896
Symptoms. Treatment.	
2. <i>Tubercle</i> . . . . .	896
3. <i>Morbid Growths</i> . . . . .	896
4. <i>Dilatation</i> . . . . .	897
Symptoms. Treatment.	
5. <i>Dilatation of Müllerian duct</i> . . . . .	898
II. DISEASES OF THE UTERUS, FALLOPIAN TUBES, AND OVARIES . . . . .	898
A. <i>Metritis and Oophoritis</i> . . . . .	898
Causation and morbid anatomy. Symptoms.	
B. <i>Morbid Growths</i> . . . . .	899
1. <i>Tubercle</i> . Symptoms. 2. <i>Myomata</i> . Symptoms. 3. <i>Malignant disease</i> . Symptoms.	
C. <i>Cystic Tumours</i> . . . . .	900
Causation and morbid anatomy. 1. <i>Dilatation of the uterus</i> . 2. <i>Dilatation of the Fallopian tube</i> . 3. <i>Parovarian cysts</i> . 4. <i>Ovarian cysts</i> . Symptoms and progress. Treatment.	
III. DISEASES OF THE PELVIC PERITONEUM AND CONNECTIVE TISSUE . . . . .	904

	PAGE
CHAP. VII.—DISEASES OF THE ORGANS OF LOCOMOTION	906
I. RHEUMATISM ( <i>Rheumatic Fever</i> ) . . . . .	906
Definition. Causation. Morbid anatomy. Symptoms and progress. Pathology. Treatment.	
II. RHEUMATOID ARTHRITIS ( <i>Chronic Rheumatic Arthritis</i> ) . . . . .	915
Definition. Causation. Morbid anatomy. Symptoms and progress. Pathology. Treatment.	
III. GOUT ( <i>Podagra</i> ) . . . . .	917
Definition. Causation. Morbid anatomy. Symptoms and progress. Pathology. Treatment.	
IV. RICKETS ( <i>Rachitis</i> ) . . . . .	927
Definition. Causation. Morbid anatomy and pathology. symptoms and progress. Treatment.	
V. ACUTE RICKETS . . . . .	933
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
VI. MOLLITIES OSSIIUM ( <i>Osteo-malacia</i> ) . . . . .	935
Definition and causation. Morbid anatomy and pathology. Symptoms and progress. Treatment.	
VII. ACROMEGALY . . . . .	937

CHAP. VIII.—DISEASES OF THE NERVOUS SYSTEM . 939

I. INTRODUCTORY REMARKS . . . . .	939
A. <i>Anatomy and Physiology</i> . . . . .	939
1. Membranes of brain and cord. 2. Ventricles of brain and cord. 3. Cerebral hemispheres: <i>a.</i> fissures; <i>b.</i> convolutions. 4. Ganglia at base of brain. 5. Cerebellum and its peduncles. 6. Spinal cord. 7. Medulla oblongata. 8. Cerebro-spinal nerves. 9. Résumé. 10. Localisation of function: <i>a.</i> cerebral hemisphere; <i>b.</i> corpus striatum; <i>c.</i> optic thalamus; <i>d.</i> cerebellum; <i>e.</i> corpora quadrigemina; <i>f.</i> medulla oblongata; <i>g.</i> cord; <i>h.</i> olfactory and optic nerves. 11. Sympathetic system. 12. Arteries of brain. 13. Veins of brain.	
B. <i>Pathology</i> . . . . .	964
1. <i>Motor Paralysis. Paresis</i> . . . . .	964
<i>a. Cerebral paralysis.</i> i. General paralysis. ii. Hemiplegia.	
<i>b. Bulbar paralysis.</i> <i>c. Spinal paralysis</i> —paraplegia. <i>d. Nerve paralysis.</i> <i>e. Disease of the cerebellum.</i> <i>f. Condition of muscles in motor paralysis.</i> i. Tone. ii. Electric contractility and irritability. iii. Nutrition. iv. Reflex action. v. Irritability.	
2. <i>Anæsthesia. Analgesia</i> . . . . .	974
<i>a. Cerebral anæsthesia.</i> i. General anæsthesia. ii. Hemianæsthesia. <i>b. Bulbar anæsthesia.</i> <i>c. Spinal anæsthesia.</i> <i>d. Nerve anæsthesia.</i>	

3. <i>Convulsions. Spasms</i> . . . . .	977
4. <i>Hyperæsthesia Dysæsthesia</i> . . . . .	980
5. <i>Influence of Nervous Diseases over the Nutritive Processes</i> . . . . .	981
<i>a. Sympathetic system. b. Cerebro-spinal system. i. Muscles.</i> <i>ii. Joints and bones. iii. Skin; bed-sores. iv. Viscera. Re-</i> <i>capitulation.</i>	
6. <i>Ascending, Descending, and Collateral Lesions</i> . . . . .	986
7. <i>Central and Reflex Consequences of Lesions of the Nerves</i> . . . . .	987
8. <i>Headache</i> . . . . .	988
9. <i>Vertigo</i> . . . . .	989
10. <i>Paralytic Affections of Speech (Aphasia. Aphemia. Amnesia)</i> . . . . .	990
Varieties.	
11. <i>Stammering</i> . . . . .	996
12. <i>Mental and Emotional Disturbances</i> . . . . .	998
C. <i>Electricity in Nervous Diseases</i> . . . . .	998
For diagnostic purposes. Therapeutic uses.	
II. INFLAMMATION OF THE CEREBRAL AND SPINAL DURA MATER.	
PACHYMEINGITIS . . . . .	1006
Causation. Morbid anatomy: 1. Cerebral dura mater; 2.	
Theca vertebralis; 3. Pachymeningitis. Symptoms and pro-	
gress: 1. Acute inflammation of the cerebral dura mater; 2.	
Pachymeningitis of the cerebral dura mater; 3. Acute general	
inflammation of the theca vertebralis; 4. Caries of the vertebræ;	
5. Cervical pachymeningitis. Treatment.	
III. CEREBRAL AND SPINAL MENINGITIS. TUBERCULAR MENINGITIS	
( <i>Acute Hydrocephalus</i> ) . . . . .	1015
Causation. Morbid anatomy: 1. Cerebral meningitis. 2.	
Tubercular meningitis; 3. Spinal meningitis. Symptoms and	
progress: 1. Cerebral meningitis; 2. Spinal meningitis. Treat-	
ment.	
IV. ENCEPHALITIS AND MYELITIS . . . . .	1025
( <i>Inflammation and suppuration of the Brain and Cord.</i> )	
Causation. Morbid anatomy: 1. Encephalitis; 2. Myelitis.	
Symptoms and progress: 1. Encephalitis; 2. Myelitis. Treat-	
ment.	
V. SYSTEM DISEASES DEPENDENT ON ACUTE INFLAMMATION, ON	
CHRONIC INFLAMMATION OR SCLEROSIS, AND ON DEGENERATIVE	
CHANGES . . . . .	1032
A. <i>Infantile Spinal Paralysis (Infantile Paralysis. Essential</i>	
<i>Paralysis. Acute Anterior Poliomyelitis)</i> . . . . .	1034
Definition. Causation. Morbid anatomy. Symptoms and	
progress. Treatment.	
B. <i>Adult Spinal Paralysis (Acute Anterior Poliomyelitis)</i> . . . . .	1038

	PAGE
C. <i>Acute Ascending Spinal Paralysis</i> . . . . .	1038
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
D. <i>Progressive Muscular Atrophy (Wasting Palsy, Chronic Anterior Poliomyelitis)</i> . . . . .	1040
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
E. <i>Lateral Sclerosis (Spasmodic Spinal Paralysis)</i> . . . . .	1043
Definition. Causation. Morbid anatomy. Symptoms and progress. 1. Secondary lateral sclerosis. ( <i>Amyotrophie spinale deutéropathique</i> ). 2. Idiopathic lateral sclerosis. a. <i>Spasmodic tabes dorsalis</i> . b. <i>Sclérose latérale amyotrophique</i> . Treatment.	
F. <i>Tabes Dorsalis (Locomotor Ataxy)</i> . . . . .	1049
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
G. <i>Glosso-labio-laryngeal Palsy</i> . . . . .	1057
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
H. <i>Ophthalmoplegia Interna and Externa</i> . . . . .	1060
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
I. <i>Disseminated Sclerosis (Multiple Sclerosis)</i> . . . . .	1063
Definition. Causation. Morbid anatomy. Symptoms and progress. 1. Rhythmical tremors; 2. Affections of the eyes; 3. Defect of speech; 4. Vertigo; 5. Paresis of limbs; 6. Contraction of limbs; 7. Expression and mental condition. Stages. Treatment.	
J. <i>Friedreich's Disease</i> . . . . .	1069
Definition. Causation. Morbid anatomy. Symptoms and progress.	
VI. MULTIPLE NEURITIS. . . . .	1070
Definition. Causation. Morbid anatomy. Symptoms and progress. 1. <i>Alcoholic paralysis</i> ; 2. <i>Idiopathic</i> ; 3. <i>Kakke or Beri-beri</i> ; 4. <i>Diphtheritic paralysis</i> ; 5. <i>In system diseases</i> . Treatment.	
VII. PARALYSIS AGITANS ( <i>Shaking Palsy</i> ) . . . . .	1075
Definition. Causation. Morbid anatomy. Symptoms and progress. Treatment.	
VIII. PSEUDO-HYPERTROPHIC PARALYSIS . . . . .	1079
Definition. Causation. Morbid anatomy. Symptoms and progress. Pathology. Treatment.	
IX. THOMSEN'S DISEASE . . . . .	1082
Definition. Causation. Symptoms and progress.	

	PAGE
X. MORBID GROWTHS. -ANEURYSMS. ENTOZOA . . . . .	1083
Morbid anatomy; 1. <i>Tubercle</i> ; 2. <i>Syphilis</i> ; 3. <i>Neoplasms</i> ; <i>a. myxoma</i> ; <i>b. glioma</i> ; <i>c. sarcoma</i> ; <i>d. carcinoma</i> ; 4. <i>Entozoa</i> ; <i>a. cysticerci</i> ; <i>b. hydatids</i> ; 5. <i>Aneurysms</i> . Symptoms and progress: 1. Brain: vertigo; headache; vomiting; slowness of pulse; hemiplegia and hemianæsthesia; local paralyses; impli- cation of sensory nerves; convulsions and spasms; intellectual and emotional disorders; obstruction of venous sinuses. 2. Spinal cord: <i>a. in substance of cord</i> ; <i>b. in meninges</i> ; <i>c. in</i> <i>tissues external to meninges</i> . Treatment.	
XI. CEREBRAL AND SPINAL HEMORRHAGE ( <i>Apoplexy</i> ) . . . . .	1094
Causation. Morbid anatomy: 1. hemorrhage on surface; 2. hemorrhage into the brain; 3. into the cord. Symptoms and progress: 1. in cerebral hemorrhage; 2. in spinal hemorrhage. Treatment.	
XII. OBSTRUCTION OF CEREBRAL ARTERIES ( <i>Thrombosis. Embolism.</i> <i>Softening</i> ) . . . . .	1104
Causation and morbid anatomy. Symptoms and progress. Treatment.	
XIII. HYDROCEPHALUS AND HYDRORRHACHIS ( <i>Cerebral and Spinal</i> <i>Dropsy</i> ) . . . . .	1110
Causation and morbid anatomy: 1. <i>a. Hydromeningocele, hy-</i> <i>drencephalocoele</i> ; <i>b. Spina bifida</i> : 2. <i>a. Chronic hydrocephalus</i> ; <i>b. Internal hydrorrhachis</i> . Symptoms and progress. Treat- ment.	
XIV. CHOREA ( <i>St. Vitus's Dance</i> ) . . . . .	1116
Definition. Causation. Symptoms and progress. Morbid anatomy and pathology. Treatment.	
XV. EPILEPSY. ECLAMPSIA. INFANTILE CONVULSIONS . . . . .	1123
A. <i>Epilepsy (Morbus comitialis vel sacer)</i> . . . . .	1123
Definition. Causation. Symptoms and progress. Description of <i>epilepsia gravior</i> or the <i>haut mal</i> . Description of abortive fit and of the <i>petit mal</i> or <i>epileptic vertigo</i> . The <i>status epilepticus</i> . Recurrence of fits. Causes determining the occurrence of fits in epileptics. Condition of epileptics in intervals between attacks. <i>Epileptic mania</i> . Diagnosis. Feigned epilepsy. Morbid anatomy and pathology. Treatment.	
B. <i>Eclampsia</i> . . . . .	1135
Definition and causation. Symptoms and progress. Treat- ment.	
C. <i>Infantile Convulsions</i> . . . . .	1136
Definition and causation. Symptoms and progress. Treat- ment.	
XVI. HYSTERIA . . . . .	1138
Definition. Causation. Symptoms and progress: 1. convul- sions and spasms; 2. hyperæsthesia; 3. anæsthesia; 4. para-	

lytic conditions; 5. affections of speech; 6. affections of the larynx and air-passages; 7. affections of the alimentary canal; 8. affections of the urinary organs; 9. affections of the reproductive system; 10. affections of the spine, joints, and mammæ; 11. hysterical fever; 12. spinal irritation. Diagnosis. Pathology. Treatment.

XVII. CATALEPSY, ECSTASY, SOMNAMBULISM, AND OTHER CONDITIONS

ALLIED TO HYSTERIA . . . . . 1152

1. *Rhythmical and other Methodical Movements* . . . . . 1152

2. *Catalepsy* . . . . . 1152

3. *Ecstasy* . . . . . 1153

4. *Somnambulism* . . . . . 1153

5. *Certain obscure cases* . . . . . 1154  
Treatment.

XVIII. TETANUS (*Trismus. Lock-jaw*) . . . . . 1154

Definition. Causation. Symptoms and progress. *Trismus or lock-jaw. Opisthotonos. Emprosthotonos. Pleurosthotonos.* Diagnosis. Morbid anatomy. Treatment.

XIX. TETANY . . . . . 1160

Definition. Causation. Symptoms and progress. Morbid anatomy and pathology. Treatment.

XX. CONGESTION. ANÆMIA. SUNSTROKE . . . . . 1162

A. *Congestion and Anæmia* . . . . . 1162

Symptoms: 1. *Delirium tremens.* 2. *Insanity.* 3. *Eclampsia.*

4. *Apoplexy and paralysis.* Treatment.

B. *Sunstroke (Coup de Soleil. Calenture. Insolatio)* . . . . . 1165

Definition. Causation. Symptoms and progress. Morbid anatomy and pathology. Treatment.

XXI. MEGRIM (*Migraine. Hemicrania. Sick-headache*) . . . . . 1166

Definition. Causation. Symptoms and progress. Pathology. Treatment.

XXII. MENIÈRE'S DISEASE (*Aural Vertigo*) . . . . . 1170

Definition. Causation and pathology. Symptoms and progress. Treatment.

XXIII. LOCAL PARALYSES . . . . . 1172

A. *Paralysis of the Third, Fourth, and Sixth, or Oculo-Motor Nerves* . . . . . 1172

Causation. Symptoms and diagnosis. Treatment.

B. *Paralysis of the Fifth Nerve* . . . . . 1176

Causation. Symptoms and diagnosis. Treatment.

C. *Paralysis of the Portio Dura (Bell's Paralysis)* . . . . . 1177

Causation. Symptoms and diagnosis. Treatment.

D. <i>Paralysis of the Spinal Nerves</i> . . . . .	1181
Causation. Symptoms and diagnosis : 1. Deltoid rheumatism ;	
2. Paralysis of musculo-spiral nerve. Treatment.	

XXIV. LOCAL FUNCTIONAL SPASM AND PARALYSIS. WRITER'S CRAMP, WRY-NECK, HISTRIONIC SPASM, &c. . . . .	1182
Definition. Causation. Symptoms and diagnosis : 1. <i>Writer's</i> <i>cramp</i> ; 2. <i>Spasmodic wry-neck, &amp;c.</i> Pathology. Treatment.	

XXV. NEURALGIA. TIC DOULOUREUX. SCIATICA . . . . .	1185
Definition. Causation. Symptoms and progress : 1. <i>Tic dou-</i> <i>loureux</i> ; 2. <i>Sciatica</i> and other forms. Treatment.	

XXVI. MADNESS ( <i>Insanity</i> ) . . . . .	1190
Definition . . . . .	1190
Causation . . . . .	1191
1. Predisposing causes. 2. Exciting causes.	
Symptoms and progress . . . . .	1194
A. <i>General Description</i> . . . . .	1194
1. Disorders of sensation. 2. Intellectual disorders ; destruc- tive tendencies. 3. Disorders of movement. 4. Resemblances between insanity and dreaming.	
B. <i>Special Description</i> . . . . .	1203
1. <i>Melancholia</i> . . . . .	1204
<i>a.</i> Hypochondriasis ; <i>b.</i> melancholia with stupor ; <i>c.</i> melan- cholia with excitement.	
2. <i>Mania</i> . . . . .	1208
Delirium tremens. Acute delirium. Recurrent mania. Folie circulaire. Mania sine delirio.	
3. <i>Monomania</i> . . . . .	1212
4. <i>Dementia</i> . . . . .	1214
Varieties of dementia.	
5. <i>General Paralysis</i> . . . . .	1217
<i>a.</i> Congestive ; <i>b.</i> paralytic ; <i>c.</i> expansive ; <i>d.</i> melancholic.	
6. <i>Idiocy</i> . . . . .	1222
C. <i>Madness arising under special physical conditions of</i> <i>system</i> . . . . .	1223
1. Alcoholic insanity. 2. Puerperal insanity. 3. Insanity of self-abuse. 4. Insanity of febrile disorders.	
D. <i>Prognosis</i> . . . . .	1225
Pathology and morbid anatomy . . . . .	1226
Treatment . . . . .	1229
1. Moral treatment. 2. Therapeutical treatment.	
Legal Management of Lunatics . . . . .	1232

INDEX . . . . .	1241

PART I

GENERAL PATHOLOGY

# GENERAL PATHOLOGY

## I. THE DEFINITION OF DISEASE

**PATHOLOGY**, or the physiology of disease, is the science of life under morbid or abnormal conditions. This science, and the arts of applying it in the detection and in the alleviation or cure of disease, and in its prevention, form the subject-matter of works on medicine and surgery.

The question, then, 'What is disease?' naturally arises on the very threshold of a treatise on the practice of medicine. But although, doubtless, every physician has a notion, sufficiently clear for the practical purposes of his art, of what is implied in the word, the question is one which by no means admits of a ready and explicit answer. Disease, in some at least of its forms, has been regarded by many persons, and is probably still regarded by some, as a real thing or entity. This view implies that it can be either cut out by the anatomist, or extracted by the chemist, or excreted by the patient himself, or in some other way separated from his body, so as to become capable of independent existence and recognition; and might be supported by reference to the discharge of an intestinal worm or the removal of a vesical calculus, or to a patch of psoriasis, an epitheliomatous tumour, a malformed heart, or probably any other so-called 'local' disease. A little thought, however, will satisfy the mind that the intestinal worm, or the calculus, is of itself the mere cause of disease, and not disease; and that the patch of psoriasis, the epitheliomatous tumour, or the malformed heart, is simply a morbid fragment of the body, and no more the disease itself than the patient who is suffering from scarlet fever or syphilis is the actual embodiment of either of these latter two affections. But, indeed, the opinion that disease is an entity has now been abandoned by all thoughtful physicians. Another view of disease is, that it consists in any deviation from the healthy state, or (at greater length) in any condition of the entire system, or of any part of it, attended with impairment or derangement of structure or function, or both, and tending to render life uneasy, burdensome, or useless, or to shorten it. It would be difficult perhaps to dispute the accuracy of this definition so far as it goes; at the same time it is obvious that we gain

examined ; as, for example, where mechanical impediments occur in the course of the bowel, urethra, ducts of glands, or other tubular organs ; or where poisons received into the stomach act directly upon that viscus, or on distant organs in which they are deposited, or through which they circulate ; or where, finally, pathological results follow from excess, deficiency, or unwholesomeness of diet.

Now, in every one of the above examples, it is beyond dispute that neither the collective morbid phenomena or symptoms which indicate the presence of disease, taken by themselves, nor the morbid cause on which these phenomena depend, taken by itself, constitutes a disease ; that, alone, they are simply factors of disease ; and that in each case our conception of a disease is fulfilled only when the cause and its results are, so to speak, welded mentally into one common whole. And hence, if these views be generally true, disease may be defined as *a complex of some deleterious agency acting on the body, and of the phenomena (actual or potential) due to the operation of that agency.*

Regarding it, not as a matter of idle curiosity, but as one of fundamental importance for a clear appreciation of the aims and limits of diagnosis and treatment, that we should have a distinct comprehension of what we mean by disease, we shall pursue the question yet further, mainly with the object of determining how far the word disease is properly applicable (as it often is applied in practice) to mere symptoms or secondary phenomena or incidents of disease.

All diseases involve, some in a greater some in a lesser degree, certain groups of pathological consequences immediately traceable to their respective morbid causes ; but these primary pathological consequences themselves tend to evoke others, these again a tertiary series, and so on continuously. Thus, a person with carcinoma of the bowel may, as a consequence, have stricture, perforation, involvement of the glands occupying the retro-peritoneal tissue and gastro-hepatic omentum, or that form of cachexia which cancerous disease so frequently induces ; and, as a result of these several secondary morbid conditions, various other affections, such as enteritis, peritonitis, jaundice, ascites, melæna, thrombosis, and anasarca.

Now all these phenomena, and many others which might be enumerated, are obviously component parts of the carcinomatous affection from which the patient is suffering, and may be regarded as symptoms or incidents of that affection ; but many of them are not unfrequently also looked upon as quasi-independent diseases, and treated as such. There is no doubt that they are not diseases. They are clearly, however, elements of disease ; and inasmuch as each one of them arises out of some immediately antecedent abnormal condition which is its direct cause, they do obviously enough, in association with their respective causes, fall severally within our definition of disease. Hence the affection which has been selected for illustration (and manifestly also all other primary diseases) may be considered to comprise or involve a number of what, regarded from one point of view, are symptoms or phenomena which are

essential parts of it; regarded from another point of view are component parts or factors of secondary or subordinate diseases, issuing in collateral lines of descent from a common ancestral cause.

---

## II. THE ÆTIOLOGY OF DISEASE

THE causes of disease have been divided by authors into three classes, namely, the *predisposing*, the *exciting*, and the *proximate*: the first class comprising those conditions which so modify the health of the patient as to render him apt, or predispose him, to contract the disease, to the specific influence of which he happens to be exposed; the second, those causes which immediately impart or excite disease, and give it its specific character; the third, those morbid processes which the action of the exciting cause calls into play, and to which the symptoms of disease are supposed to be directly due. The proximate cause indeed is often, though erroneously, said to be the disease itself. We will illustrate the above distinctions by an example. A woman, who has frequently been exposed to the contagion of scarlet fever without taking the disease, is again exposed at the period of childbirth, and now suffers from a virulent attack. Here, parturition, which renders women peculiarly susceptible of the contagious fevers, is the predisposing cause, the scarlatinal contagium is the exciting cause, and the inflammatory processes going on in the skin, tonsils, and elsewhere, are the proximate causes of most of the symptoms which the patient manifests. But the exciting cause of the scarlet fever is obviously the proximate cause of that disease, and the proximate causes of its several secondary phenomena are just as obviously their exciting causes.

The distinction between the exciting cause and the proximate cause is thus purely artificial. That between the predisposing cause and the exciting cause, on the other hand, is in general well marked: and doubtless if we had an accurate knowledge of the causation of disease, the universality of the truth which underlies these terms would be beyond dispute. As it is, however, doubts or difficulties as to their meaning and application are apt to present themselves.

An example will explain our meaning. A man, who has been suffering from privation, is exposed to malarial influence, and contracts ague. In this case, clearly enough, privation is the predisposing cause, malaria the exciting cause. But after a time the ague leaves him, and he is apparently restored to health; and he continues well, until perchance from exposure to the weather in some non-malarious district he catches cold, and straightway experiences another attack of ague. Now which in the latter case should be regarded as the exciting cause? The answer will probably be, 'Exposure to cold and wet,' an answer which necessarily implies that on this occasion malaria is the predisposing cause. Yet,

notwithstanding, malaria is equally in both cases the specific cause of the disease, and acts (as we have no reason to doubt) in both cases in a precisely similar manner.

On the whole, however, we mean by exciting cause the specific cause, or element, in disease: that cause (the contagium of an exanthem, the virus of rabies, the parasite of a tinea) which stamps its individuality on the group of morbid processes which ensue, and constitutes with them a definite or specific disease; and by predisposing causes we mean those general non-specific conditions which by their influence so modify the health of the system, or of parts of it, as to render them (so to speak) a specially suitable soil for the growth of certain diseases, supposing the germs of these diseases happen to become implanted in them.

#### A. PREDISPOSING CAUSES OF DISEASE

We shall not discuss the subject of predisposing causes at any length, although it is one of surpassing interest, especially perhaps in relation to preventive medicine; but shall content ourselves with enumerating and considering briefly some of the more important and more generally recognised amongst them.

1. *The influence of age* is very remarkable. The period of growth and development, commencing with birth and terminating with the attainment of maturity, and comprising the important physiological epochs of the first dentition, the second dentition, and the unfolding of the sexual system, not only is attended with a general aptitude for diseases having a special connection with the physiological processes (general or special) which are going on then, but is liable for less obvious reasons to the attacks of various maladies of other kinds. In early infancy a remarkable tendency exists to disturbances of the alimentary canal; and to these a very large proportion of infantile mortality is due. Again, at this time, and especially during the period of the first dentition, epileptiform convulsions are of peculiar frequency. Rickets is a disease which can manifest itself only during the period of growth of the osseous system, and does in fact occur during the first few years of childhood. It is about this time also that pseudo-hypertrophic paralysis is most commonly met with. True asthma generally comes on in childhood, and is apt to disappear before maturity is reached. Chorea affects in large proportion young persons between the ages of 8 or 9 and 15 or 16; and epilepsy, when not immediately traceable to infantile convulsions, commences very frequently about the same time. Acute rheumatism, again, and scrofulous diseases are disproportionately common in young persons. Further, some parasites, such as thread-worms and the trichophyton tonsurans, are peculiarly prone to affect children. Few special liabilities to disease mark the period of maturity, excepting such as are connected with difference of sex, or arise out of habits of life and other circumstances which have only an accidental connection with age. But as the decline of life approaches, and during its continuance, many disorders, and mainly such

as are connected with the decay and degeneration of tissues and organs, manifest themselves. Thus, the central nervous system becomes affected, and feebleness of mind or fatuity and paralysis supervene ; or the heart undergoes morbid changes, and dropsies and hemorrhages result ; or the vessels get weakened, and aneurysms and ruptures with extravasations of blood occur ; or the stomach, liver, or kidneys suffer, and cease to act efficiently. Gout, too, should probably be included among the proclivities of advancing years.

2. *The differences in the organisation of the sexes* necessitate of course differences as regards some of the diseases to which they are respectively liable. In one sex we meet with disorders connected with the uterus and ovaries, disorders of menstruation, pregnancy, and lactation ; in the other sex affections which are peculiar to the male organs of generation. But besides these necessary differences, there are others which are much more difficult to explain, and yet are nearly as constant. Thus, chlorosis and hysteria, and nervous disorders related to hysteria, are the almost exclusive heritage of females. And certain other affections which occur in both sexes are yet, for no sufficient reason (so far as we can see), far more prone to attack the one than the other. For example, erythema nodosum, and exophthalmic goitre, and goitre itself, are mainly feminine disorders, while colour-blindness and stammering affect males with disproportionate frequency. It is possible of course that some of these latter differences may not be due to the influence of sex alone.

3. *Personal peculiarities*, born with the individual, and often hereditary, have an important influence over the relative liability of persons to disease. Children notoriously resemble their parents, not only in the general configuration of the body, but in features, expression, complexion, and mental attributes. Trivial peculiarities in the form of some feature, in the quality of the laugh, small oddities of manner or of gesture, are perpetuated in families. It is not surprising therefore that malformations and other morbid conditions and tendencies to disease should be transmitted also. It is important, however, to note : first, that such inherited peculiarities and tendencies not unfrequently skip a generation, or appear as it were sporadically in families, so that, while out of a family of brothers and sisters some are affected and others escape, the affected and unaffected procreate indifferently healthy and unhealthy offspring ; second, that the inherited tendency to disease does not in all cases manifest itself in an exact reproduction of the morbid peculiarity of the parent ; and third, that in many cases peculiarities of constitution and special proclivities to disease appear altogether *de novo*.

In some instances the morbid condition is developed, or appears, in fetal life ; in others the child is born healthy, but with a tendency to disease, which becomes realised at some later period. As examples of the former case may be enumerated congenital malformations, idiocy and nævi. Examples of the latter case are more common and far more important for the physician, and therefore need more detailed consideration. Certain functional nervous disorders, such as insanity, epilepsy,

hysteria, asthma, neuralgia, undoubtedly run in families, and are apt in some degree to alternate, so that a parent suffering from one of them may beget children in whom one or other of the remaining members of the group replaces as it were the particular parental malady. Again, gout, tuberculosis, carcinoma and other forms of growths, all manifest a tendency to hereditariness. So do many varieties of skin-disease, such as ichthyosis, psoriasis, and acne. Degenerative affections, especially those characterised by fatty or calcareous changes, also incline to repeat themselves; and hence, in some families the members are apt to be cut off prematurely by extravasations of blood into the brain, due to degeneration of the cerebral arteries, in others the heart appears to be the selective seat of such changes. Lastly, among inherited or personal peculiarities, we must not forget certain idiosyncrasies characterised by special liability to suffer from agencies which are to most persons innocuous, or to remain unaffected by conditions which are generally inimical. The influence of the emanations from fresh hay in producing hay-asthma and of the smell of many flowers in creating nausea, the specially poisonous effects which even the smallest doses of mercury, arsenic, opium, or other drugs, and which also certain forms of food (even such wholesome meat as mutton) have upon certain individuals, the unhappy tendency which some persons seem to have to contract all the catching diseases to which they are exposed, and maybe to take the same one over and over again, and the remarkable way in which other persons seem always to escape, are common examples of the peculiarities referred to.

4. *Occupation, habits of life, quantity of food or drink, over-indulgence, privation, and even abstinence*, are all of them potent agents in modifying the constitution and rendering the frame susceptible of disease. We may quote, in exemplification of this statement, the acquired proclivity of compositors to tubercular phthisis; that of persons who lead sedentary lives to suffer from indigestion and constipation, and the effects of accumulated fat; and that of habitual eaters or drinkers to excess to become gouty, and to suffer from renal and hepatic disorders. It would be easy to multiply examples of these and like causes in the production of disease, and especially to adduce illustrations which might appear far more striking than any of the few given above—such, for example, as the occurrence in miners and others of special forms of lung-disease, in painters of dropped hand, in drinkers of cirrhosis of the liver, delirium tremens, and so on. But it is obvious that we have here examples, not of any mere predisposition which has been gradually acquired, but of the direct and specific influence of certain exciting causes to which the sufferers have been exposed.

5. *The effects of previous disease* in modifying the tendency to subsequent attacks of disease are in many cases very remarkable. In the exanthemata and allied affections an attack of any one is in a very high degree protective against subsequent attacks of the same malady. On the other hand, many inflammations tend to repeat themselves. Thus, persons who have once had erysipelas of the face generally manifest a

liability to recurrences of the same malady throughout the remainder of their lives. So it is with rheumatism, pneumonia, bronchitis, tonsillitis, catarrh, renal inflammation, and intermittent hæmaturia. And, indeed, one of the most difficult practical problems with which physicians have to deal is that of the counteraction of such acquired tendencies. But there are many disorders which engender a liability, not to their own recurrence, but to the attacks of other diseases. Thus, scarlet fever and gonorrhœa are both curiously apt to be succeeded by attacks of acute rheumatism; tuberculosis is generally believed to follow frequently on enteric fever and small-pox, and scrofulous enlargement of the cervical glands on mumps; and chorea may certainly be regarded as a sequela both of acute rheumatism and of scarlet fever. To these latter examples may be added the fact, which seems beyond dispute, that organs and parts which have been the seats of repeated or continuous attacks of inflammation, and have in consequence undergone structural changes, and so also pigmentary nævi, often prove the selective sites for the primary development of sarcomatous and other kinds of malignant growths.

It may be convenient to refer here to the special morbid predispositions of different organs and tissues. A very little acquaintance with pathology is sufficient to prove that the different parts of the system are not all equally liable, or liable in proportion to their respective bulks, vascular supply, or importance, to the same forms of disease. Thus, each one of the specific infectious fevers involves in its progress certain organs, altogether disproportionately to other organs, if not to the entire exclusion of some; parasites, whether vegetable or animal, limit their attacks more or less exclusively to certain parts, such as the skin, muscular system, liver, or intestinal canal; the inflammations of rheumatism and of gout are specially wont to seize on the ligaments and other soft parts about joints; and tumours, according to their characters, are prone to originate in different tissues—tubercle, which is so wide in its distribution, rarely, if ever, appearing in the skin, connective tissue, or muscles; and carcinoma, which is even less exclusive than tubercle in its choice of locality, yet preferring for its primary manifestation certain organs, as the uterus, the mamma, and the alimentary canal.

6. *The influence of heat and cold, of dryness and moisture, and of atmospheric impurity* in predisposing to disease is universally admitted. But here, as in some of the cases previously referred to, we are apt to confound, and it is difficult to avoid confounding, their indirect effects as predisposing agents with their direct effects as exciting causes. And further, when we come to test the relative influences of climates and seasons by their prevalent diseases, our endeavours to arrive at a just conclusion on the subject are seriously hampered by the coexistence with them (but partly no doubt arising out of them) of peculiarities of habit and modes of life, and of malaria and other special conditions of unhealthiness. Thus we shall all acknowledge the influence of temperature in the production of bronchitis, pneumonia, rheumatism, and sunstroke; but in these cases temperature probably acts as the exciting cause. Again, we

shall all be ready to allow that remittent fever, hepatitis, and dysentery are characteristic diseases of tropical climates ; but for the first malaria, not temperature, is wholly responsible, and the latter two are possibly in some cases also of malarious origin. Further, we all know, by personal experience, the ill effects of overcrowded close rooms ; and we cannot doubt that deterioration of health must result from that constant breathing of vitiated air to which the children of the urban poor are generally condemned, and we shall possibly rightly attribute much of their early sickness and prematurity of death directly or indirectly to this cause ; but it is certainly difficult accurately to identify either the morbid state which it produces directly, or the special predispositions to disease which it engenders.

It is well known that certain diseases prevail exclusively or with special severity in certain climates, and that their prevalence varies with season and also with local telluric and hygienic conditions. Yellow fever occurs in the West Indies and on the West Coast of Africa and in some few other localities ; dysentery and hepatic abscess are peculiarly diseases of tropical India ; Asiatic cholera, dengue, plague, all originate, and prevail chiefly or exclusively, in hot climates ; tubercular phthisis is one of the scourges of the temperate zone. Again, at least in our own country, thoracic inflammations are most frequent during the cold seasons of the year—acute pneumonia being probably most common in the early spring ; diarrhœal affections prevail in summer ; and many other diseases have a tendency, difficult to explain, either to undergo exacerbation or to break out, or it may be to subside, at characteristic times. Thus ague appears chiefly in spring and autumn, and psoriasis and some other forms of skin-disease have a similar tendency.

It may here be remarked that (fortunately for us) the human frame is adapted to live healthily under great varieties of climate, and under great extremes of heat and cold ; and that the effects of climate in the production of disease are probably due less to simple cold or heat, dryness or moisture, than to the neglect, on change of climate, to adapt our habits of life to the altered circumstances in which we find ourselves, and to sudden and unprepared-for variations of temperature.

7. In close connection with the subject under consideration is the question of variation in the so-called ‘ epidemic constitution ’ of different years, and that of change in the ‘ type of disease.’

By the term *epidemic constitution*, Sydenham, who first employed it, meant a peculiar variability of the atmosphere, determined by special telluric conditions ; to which, as a specific cause, he attributed the development of epidemic diseases, such as small-pox, scarlet fever, measles, and plague ; and by variations in which he explained the epidemic prevalence of one or other of these diseases, and a tendency (which he believed to exist) for all indifferent diseases occurring during an epidemic to be modified under its influence and to assume some of its characteristics. The advance of pathological knowledge since his day has proved that most, if not all, epidemic disorders spread by contagion, and that there is

no atmospheric or telluric influence to which they are due, and nothing beyond actual contagion which can give, during the presence of Asiatic cholera, or of small-pox and the like, any of the special attributes of these diseases to other prevalent diseases. Nevertheless, it must be admitted that there is something remarkable, if not inexplicable, in the way in which diseases (not contagious and miasmatic only, but simply inflammatory also) become at irregularly recurring intervals prevalent in a high degree over wide areas. In this qualified sense the expression 'epidemic constitution' is still not unfrequently, and may on the whole be conveniently, employed.

By the term *change of type in disease* is understood, not the transformation of one epidemic disease by gradual steps into another such disease—a process in which few now believe; but a change in the quality of diseases, in virtue of which they present cycles of greater and lesser intensity of attack and of other deviations from the normal standard. Such changes are believed to depend partly on variations referrible to the disease itself, partly on 'epidemic constitution,' partly on cyclical changes in the constitution of mankind. There can be no doubt that differences of severity and fatality do not unfrequently characterise different epidemics of the same disease; and further, it is beyond dispute that, even during the same epidemic, some persons are attacked with much greater or much less severity than others, or have the disease in a more or less modified form; and in these senses the fact of variation in the type of disease must be fully admitted. There are many, however, who still believe that all diseases have undergone a change of type, say, during the last fifty or sixty years; that they were formerly sthenic, and were to be cured by blood-letting, whereas they have now become asthenic and demand an exactly opposite line of treatment. It would be strange if, while the old descriptions of diseases remain accurately applicable, as in fact they do, to those of the present day, and while the health of the population has been undergoing gradual improvement, as it has done (if, at least, we may judge by the diminishing death-rates and the improved circumstances of the people), the effects of these unchanged diseases on the improved constitutions should be to render these latter more helpless during their attacks, and more likely to succumb from sheer debility. Many will be disposed to admit that the change of type has been rather in the medical practitioner than in disease or in the bodily constitution, and that the gradual change of treatment has been due, either to the slow advance of knowledge with respect to the effects of remedies in disease, or to fashion.

## B. EXCITING CAUSES OF DISEASE

Amongst the predisposing causes of disease just passed in review are some which act at least as efficiently in the direct production of disease. We refer especially to those discussed in paragraphs 4 and 6. It is certain that to variations of temperature, combined with changes of the hygrometric condition of the atmosphere, a very large proportion of local inflammations

is immediately due. As examples may be cited common catarrh, bronchitis, pleurisy, nephritis, rheumatism, inflammation of the portio dura causing facial palsy and various affections of the skin. Again, over-indulgence in food, even though the food partaken of be fairly wholesome, not only causes sickness and diarrhoea, or other forms of gastro-intestinal disturbance, but leads ultimately to accumulation of fat, plethora, indigestion, gout, and various disorders arising out of these. So, on the other hand, deficiency of sustenance, or deficiency of essential ingredients of that sustenance, induces emaciation, anæmia, debility, degeneration, and various special disorders, the direct production of some of which has been demonstrated by experiment on the lower animals, and of which scurvy affords a notable example. Not far removed from such causes as these is the over-exercise or under-exercise, or abuse of the system, or of component parts of it. We need only refer, in proof of their efficacy, to the serious consequences which are apt to ensue on sudden and very violent muscular efforts, or on long-continued over-exertion of the muscular system, to the injurious effects of sexual excesses, which are not entirely due to seminal losses, and to the many nervous disorders which originate in overwork of the brain, in prolonged wakefulness, in the unrestrained indulgence of the passions, and the like.

Without meaning thereby to exclude the various causes which have just been enumerated from classification among them, we may, with tolerable accuracy, group the remaining specific causes of disease under the heads of *mechanical*, *chemical*, and *vital*; and we may further divide them into the *endopathic*, or those which originate within the system on which they act, and the *exopathic*, or those which attack the system from without.

1. *Mechanical Causes.* *Exopathic* mechanical causes embrace all forms of external violence, the results of which fall more particularly within the province of the surgeon. *Endopathic* mechanical causes, on the other hand, are of special importance and interest to the physician. They include mechanical obstructions of orifices or tubes, whether these obstructions be caused by thickening and contraction of their walls, by pressure on them from without, or by impacted concretions: such are intestinal stricture, hernia, intussusception, and the lodgment of gall-stones, and all similar obstructions in the ducts of the liver and pancreas, in the various urinary passages, in the larynx, trachea and bronchial tubes, at the cardiac orifices, and in the blood-vessels. They also include impediments, however originating, to the transmission of nerve-currents along the nerves, dilatations of arteries and of other tubes and cavities, perforations or ruptures of their parietes, and extravasations or effusions of blood, serum, and other matters. It is obvious, therefore, that agencies of this kind are the direct causes of a very large proportion of the local diseases to which we are liable. But it may be observed that they would probably all have been considered by the older writers as proximate rather than exciting causes of disease, and that they are in fact in no case the primary causes of the morbid processes from which patients suffer. Thus, the

person who has stricture of the œsophagus or bowel, and whose grave symptoms are all referrible to the stricture, owes his stricture to previous local inflammatory thickening, ulceration, or carcinoma ; and he, who dies from the consequences of mechanical impediment to the passage of blood through the mitral orifice, traces the affection of the mitral valve to a long antecedent attack of rheumatic fever.

2. *Chemical causes of disease* include all poisonous substances, whether they be derived from the inorganic or from the organic kingdom, and however variously they exert their influence over the system. The great majority of these are necessarily *exopathic*. Some, like the caustic alkalies and mineral acids, destroy the surfaces to which they are applied ; others, like opium, strychnia, aconite, and snake-poisons, undergo absorption, and quickly exert their chief influence on particular organs, or on the general system ; while others, again, introduced into the organism habitually and in minute quantities, slowly induce characteristic organic and other changes, and what are commonly regarded as definite diseases. Thus, dropped hand and colic, or plumbism, is the result of chronic lead poisoning ; muscular tremors are determined by the inhalation of mercurial vapours ; the fumes of phosphorus after a time cause necrosis of the jaws ; the habitual use of ergotised cereals for food is believed to bring about a peculiar form of gangrene of the lower extremities ; and possibly endemic goitre and cretinism are due to the constant slow action of some material agent. We may perhaps also include here the poisonous effects of certain articles of food (mussels, fungi, sausages, and the like) and those which flow from the habitual use of alcohol, tobacco, and opium.

*Endopathic* chemical causes are largely such as depend on defective action of the excretory organs, and the consequent retention in the system of effete matters which then act as poisons. The chief emunctories for the purification of the blood are the kidneys, liver, lungs, and skin. If the kidneys act inefficiently, urea and other excretory constituents of the urine accumulate in the blood, and by their presence there at length induce epileptiform convulsions, dropsy, anæmia, and other symptoms which collectively indicate the presence of Bright's disease. If the liver fail to discharge its normal functions, jaundice follows, and with that, and in some degree in consequence of it, many other grave symptoms. When, from mechanical or other impediment to respiration, the blood becomes overcharged with carbonic acid, lividity of surface, delirium, and coma presently supervene. The cutaneous exhalation is for the most part merely complementary to that of the lungs and kidneys ; and hence the injurious effects of its arrest are not very apparent ; at the same time, doubtless, serious consequences are often correctly attributed to its suppression. Among endopathic chemical causes must also be included various alkaloidal and other compounds developed within the system under various conditions which are at present obscure, and the many ill-defined products of decomposition which tend to accumulate in the blood in the course of the specific febrile disorders, and in many other diseases or pathological processes.

3. *Vital Causes.* We now come to speak of that important class of causes to which all contagious or infectious diseases owe their origin: causes which are specific for each specific disease; which are material; which pass in some way or other from those already affected to those who are sound, and implant themselves in their bodies; which grow and multiply therein at their expense, causing characteristic symptoms; which in a greater or less degree are capable of escaping therefrom, and of then similarly affecting a second series of healthy persons, and so on continually; and of which none (so far as we certainly know) has varied intrinsically in its effects from the earliest record of its operation down to the present time, or upon any part of the earth's surface. It is at once obvious that these causes are essentially and utterly different from those mechanical and chemical causes which have just been discussed. It is impossible to conceive of the contagiousness of a strictured bowel, an apoplectic clot, or an attack of jaundice; it is contrary to all we know of chemistry that lead or mercury, morphia or the poison of the cobra, or a dose of medicine, should multiply within the system. But here we have poisons or irritants which do multiply in the system, it may be a billion-fold, and every unit of whose product is as efficient in imparting disease as was the unit from which it sprang. These facts seem quite incompatible with any other view of the nature of these causes than that they are actual living things.

That some of them are living things is absolutely certain; we mean *parasitic animals and vegetables*. Of animal parasites, some live and swarm on the skin, or in it, and readily transfer themselves from one body to another; some live in the alimentary canal or in the solid organs, and these, though still capable of infecting other healthy persons, infect them indirectly only, and after undergoing remarkable transformations external to the body of their host, and often in the organism of some lower animal. Superficial diseases due to the presence of vegetable parasites also are highly contagious.

With regard to the *contagia*, properly so called, namely, the infectious matters to which the several exanthematous and other similar infectious fevers are due, there is far less direct evidence that they are universally living organisms. Nevertheless, that some are has been distinctly proved; and there are good reasons for believing that all others are of the same character. The evidence in favour of this view will be considered at a subsequent page.

The poison or *malaria* on which ague and remittent fever depend, although, so far as our present knowledge goes, not communicable from man to man, has a certain resemblance to the *contagia*, both in its mode of infecting the system and in the effects which mark its operations there, and hence not improbably is of a like nature with them.

It seems convenient to advert here to the fact that many inflammations, originating apparently in indifferent causes, either are inherently infectious or acquire under particular circumstances an infective character, and that they spread, like the diseases which have just been considered,

in some cases by direct contact or inoculation, in others, by atmospheric carriage. Thus, most practical medical men will readily admit the communicability of common catarrh and of tonsillitis, the contagiousness under special conditions of even idiopathic erysipelas, and the readiness with which catarrhal ophthalmia and impetigo occasionally spread. Gonorrhœa furnishes a yet more striking example of the same fact. These cases are important, because they seem to show the possibility of the spontaneous development of contagious elements within the system. It must be added, however, that a very large number of diseases, fundamentally distinct from one another, are yet linked together by the common bond of the occurrence in them of inflammation as a more or less prominent feature; that one tendency of advancing pathological knowledge is to recognise that, in a larger and larger number of so-called 'inflammations,' the inflammation is not the essential element in the disease, but merely one out of a group of several morbid phenomena, all starting from the direct influence of some specific cause; and that hence, perhaps, it may eventually be discovered, that all these catching inflammations are, in the same sense as scarlet fever or mumps, specific diseases dependent on specific causes. The constant presence of bacteria, in the blood and tissues, in erysipelas, pyæmia, and some other inflammations of an infective character, lends probability to this surmise.

*The causes of carcinoma* and other varieties of malignant disease, and indeed of proliferating tumours generally, are very obscure. It is not difficult to understand that when once a tumour, destined to be malignant, has made its appearance in any part, the subsequent development of secondary tumours in the neighbouring lymphatic glands, and in remote organs, may be due to the conveyance thither from the primary growth of prolific particles of its specific protoplasm; and that, hence, the diffusion of such tumours throughout the organism may, like the diffusion of small-pox throughout a population, be due to a contagium—but to a contagium possibly originating in the living tissues.

But this explanation throws no light on the primary causation of such growths, and of their specific distinctions from one another. The following remarks comprise most of what is known or suggested on the subject. It is certain that many tumours of different kinds appear secondarily to local injuries, and especially to local irritations which have been long continued. Among these may be enumerated warts, epithelioma, and scirrhus. It is certain, too, that many neoplasms, such as those which characterise syphilis, leprosy, and tuberculosis, are the immediate consequence of some living virus or poison with which the body has been inoculated. Many tumours resemble in their structural details the tissues in which they arise, and may be assumed to be mere local outgrowths or local hypertrophies of these tissues. But not unfrequently tumours have no structural relation whatever to the tissues among which they appear. Thus, masses of striped muscle have been found in the kidneys; and tumours containing hair, teeth, bones, and various other fœtal structures, not only in the ovary but in various other parts of the organism.

To explain the occurrence of such heterologous or complex growths it has been suggested by Cohnheim, and has been largely accepted, that they owe their origin to bits of embryonic tissue which have remained unutilised and imbedded in the developed tissues of the organism, and have resumed at a comparatively late period their latent powers of growth and development.

---

### III. PHYSIOLOGICAL PROCESSES IN HEALTH

THE processes of disease, however widely they may seem to diverge from those of health, are merely modifications of them, and their types must be sought in the normal physiological processes by which the body is developed, grows, maintains itself, and finally dies. It will be well, therefore, before considering them in detail, to pass briefly in review the physiological processes out of which they arise.

A. It is now admitted by physiologists, with almost perfect unanimity, that the first origin of every living thing, as also every living particle of the developed organism, is a viscid, homogeneous, colourless, albuminous substance, known as protoplasm or germinal matter; and that this is endowed with remarkable powers, in virtue of which, under appropriate conditions of warmth, moisture, and the like, it is capable: first, of throwing out processes or otherwise altering its form, and so, on the one hand, of investing and absorbing solid particles, and, on the other hand, of actual locomotion; second, of growing, and maintaining itself, by imbibing and appropriating the nutritious matters which surround it, while discharging whatever is superfluous, excrementitious, or effete; third, of multiplying by fission or by gemmation; and last (in dependence on its immediate parentage and other conditions), of undergoing further development or differentiation, so as to take part in the formation of organs, or itself to become an organ performing special functions.

Quiescent protoplasm generally occurs in the form of small round or oval masses, often presenting an imbedded nucleus, or several such bodies, and under many circumstances a thin membranous investment, and hence that combination of characters which we recognise in the typical nucleated cell. The earliest stages in the development of the embryo, and the earliest stages in the development of organs, are characterised by the abundant formation of cells of this kind (without, however, the investing membrane), which are hence termed embryonic cells. These bodies stand, therefore, at the bottom of all growth and all development; and it is by their multiplication and by the changes which they effect, or undergo, that the complex organism of the body is gradually evolved and finally perfected. Thus, in the area germinativa or blastoderm the embryonic cells arrange themselves in three layers: the uppermost or epiblast, the undermost or hypoblast, and an intermediate layer, the mesoblast. And, by a process of development or differentiation, are gradually produced: from the cells of the epiblast, the central and peripheral

nervous organs, the organs of sense, and the epidermis with its appendages; from those of the hypoblast, the epithelial linings of the alimentary canal and air-passages and the various glandular organs which communicate therewith; and from those of the intermediate layer, the vascular system, with the ductless glands, the urinary and generative organs, and the muscular, osseous, and connective tissues.

B. The result of the processes here adverted to is the formation of a series of simple tissues, which group themselves here and there into complex specialised masses, named organs. These tissues may be arranged, according to Virchow, in three categories—the *epithelial*, the *connective*, and *those of a higher grade*.

1. The tissues belonging to the *first category (the epithelial)* are evolved mainly from the epiblast and hypoblast, and comprise: the epidermis, with the hair, nails, and sebaceous and sudoriparous glands; the epithelial lining of the gastro-intestinal mucous membrane, with that of the hepatic ducts and other glandular organs connected with that membrane; the genito-urinary and pulmonary epithelia; and the endothelia of the serous and synovial cavities of the body, blood-vessels, and lymphatics. In all these cases, or in nearly all of them, the tissue is composed of typical nucleated cells (that is, of masses of protoplasm containing nuclei and invested in membrane) so arranged as to be in exact contact with one another. Minor differences, yet of great practical importance, are observed between the cells of different epithelia; thus they vary largely in size and form, and in the thickness and other special characters of their membranous investment. In the case of the outer layers of the epidermis and hairs, nuclei and protoplasm wholly disappear, and each cell becomes a mere lifeless horny flake. Epithelia subserve various functions: some, as those of the skin and blood-vessels, are merely protective; others, as that of the mucous surface of the alimentary canal, absorb; while those of glandular organs either manufacture and secrete products serviceable to the economy, or separate from the blood and excrete matters which are effete or injurious.

2. The tissues of the *second category (the connective)* are developed almost exclusively from the mesoblast, and pervade all parts of the body, with the exception of the epithelia, forming a kind of network, in the interstices of which the higher tissues and the elements of organs are contained. They consist of nucleated masses of protoplasm, which are often exceedingly minute, always surrounded by a wall of greater or less thickness, and either rounded and isolated from one another, or stellate and furnished with processes communicating with those of neighbouring cells. The essential morphological distinction between epithelium and connective tissue is, that in the former the cells are in absolute contact, in the latter they are separated from one another to a greater or less degree by some intervening substance: either an unorganised or lifeless deposit, or portions of the higher living tissues. According to the nature and amount of this intervening substance, or to peculiarities presented by the cells, connective tissues may be divided into several varieties. In ordinary

connective tissue, as also in fasciæ and tendons, the protoplasm is scanty and stellate; and the intervals, which are large, are occupied by wavy bands of white fibrous tissue and yellow elastic fibre, both of which are either simple secretions from the living protoplasmic masses, or the mummies of defunct cells. This variety of connective tissue yields gelatine. In common cartilage, the cells are round or oval, and separated from one another by a dense homogeneous elastic substance, which appears to be formed by the progressive thickening of the cell-walls and by their coalescence, and yields chondrine. In bone, the lacunæ and canaliculi mark the position of the cells and their radiating processes, the proper constituents of the bone occupying the spaces which these include. The central nervous organs and the lymphatic glands possess a peculiar form of connective tissue termed 'retiform,' in which the essential elements of these organs represent the separating material, and in which the proper cellular elements of the connective tissue are minute and stellate, and the rays passing between them are delicate and homogeneous, and enclose exceedingly small spaces. Mucous connective tissue, which is abundant in the developing fœtus, is represented at birth by the tissue of the umbilical cord, and throughout the remainder of life only by the vitreous humour of the eye. In this the intermediate substance is fluid (mucus in fact) and contains mucine. Lastly, passing by some unimportant modifications of connective tissue, it may be pointed out that, in the choroid, spinal pia mater, and elsewhere, the proper cells of this tissue contain pigment, and that in many regions they are distended with oil. In the former case, we have pigmental tissue; in the latter, fat.

It is upon the essential elements of the connective tissue (namely, the protoplasmic particles, or cells, and the processes springing from them, which, with certain modifications of character, are distributed nearly universally throughout the organism) that, according to Virchow, the action, growth, and maintenance of the organism immediately depend. And just as (to take bone for an illustration) we find certain districts or territories (the Haversian systems) under the nutritive governance of particular blood-vessels, so we find still smaller territories within them (the lacunar systems) over the welfare of each of which a single cell appears to preside. The latter are termed by Virchow 'cell-districts.'

3. The *third category* of tissues comprises mostly those which are tubular, and formed either by the juxtaposition and coalescence of cells, or of cells or protoplasm which have in some other manner undergone a high degree of specialisation. Among them we may name nerve-cells, and nerves, striped and unstriped muscular fibres, capillary vessels, and lymphatics.

4. Lastly, *complex organs*, such as muscles, bones, glands, brain, and the like, are formed by the association, in various degrees of complexity, of several of the above-enumerated tissues.

Thus, the organism may be regarded as a combination of vital and non-vital elements: whereof the latter comprise various more or less complex chemical compounds, which have been prepared and deposited

through the agency of the living matter, and whose subsequent changes and duration are regulated by the action of the living elements in their immediate vicinity; and whereof the vital elements are the protoplasmic masses or nucleated cells, which, thickly disseminated, carry on between them all the living functions. These form the universal network of connective-tissue corpuscles; the laminated aggregations constituting the various epithelia, and endothelia, and the walls of capillary vessels and lymphatics; the massive accumulations observed in the central nervous organs, liver, lymphatics, and other glands; probably striped muscular fibre, and the axis-cylinders and peripheral ends of nerves; and lastly, the corpuscles which are free in the circulating fluids.

It is important to note that the vital properties of protoplasm differ in degree, and in quality, according to its age and the functions to which, by process of development, it has become subservient. Thus, embryonic protoplasm, and its nearest representatives in the mature organism (namely leucocytes and connective-tissue corpuscles), especially possess the power of multiplication and of differential development; whereas muscular fibres and nerve-cells, which stand at the opposite extremity of the scale, probably never, at any rate in health, undergo proliferation or development except in their own special grooves.

C. The development, growth, and maintenance, therefore, of the entire organism depend essentially on the healthy circumstances, as to nutrition and the like, of the protoplasmic elements which constitute its living parts. All actively living matter is unstable and short-lived, and needs for the due performance of its vital acts (which are always attended with a certain amount of waste of tissue) suitable food, which it can imbibe and transmute into its own substance, so as at least to supply the place of that which was lost. But it needs, also, the removal of the spent nutritious fluids in which it is bathed, and of those effete and excrementitious matters which it continually emits.

1. For the purpose of providing a constant supply of nutriment, we have the blood, impelled by the heart, slowly coursing through the capillary blood-vessels, and ever sweating through their delicate parietes into the extravascular tissues around; and for the purpose of maintaining a constant removal of the spent pabulum, and of effete matters, we have the extravascular fluids ever undergoing absorption, partly by the agency of the venous radicles, but mainly by the lymphatic vessels, which have their origin in the meshes of the capillary network, and in the very spaces in which the protoplasmic elements themselves are situated.

2. The nutritious matters of the blood are supplied to it primarily from the alimentary canal. Food, after having been triturated and swallowed and acted on by the secretions of the various glandular organs which discharge their contents into the stomach and bowels, is absorbed at the surface of the mucous membrane: the fluid and more readily diffusible parts by the capillary blood-vessels, the fatty and albuminous matters by the lymphatics. Those substances which enter by the former route, after passing through the liver and perhaps undergoing some change there,

mingle with the general mass of the blood ; those which enter by the lymphatics first traverse the lymphatic glands, carrying thence with them the white corpuscles which these glands manufacture, and then like the former blend with the circulating fluid. But the surplus nutriment, which escapes from the capillary vessels into the tissues external to them, is also taken up mainly by lymphatic vessels ; and this again, after passing through lymphatic glands, and deriving thence morphological elements, mingles, like that derived from the alimentary canal, with the blood-stream. Lastly, the important secretions furnished by the mucous membrane of the alimentary canal, and by the viscera which discharge into it, are reabsorbed in large proportion with the food, and thus re-enter the circulation.

3. Effete matters derived from the waste of the organism converted by the reducing agency of inspired oxygen into diffusible compounds of comparatively simple constitution dissolve in the fluids which are also the carriers of nutritious matter ; and hence are removed from the parts in which they are produced by the same channels, namely the veins and lymphatics ; then mingle with the blood ; and are finally separated from that fluid by appropriate emunctories : carbonic acid by the lungs, nitrogenous compounds and salts by the kidneys and skin, and the colouring matter of the blood by the kidneys and liver.

4. Presiding over the processes of nutrition, and to a great extent regulating them, yet itself entirely dependent upon them for the means of its material and functional activity, is the nervous system, comprising the central organs, the nerves, and the end-organs of the nerves. By means of the nerves every part of the organism, probably almost every protoplasmic mass, is brought directly or indirectly through the intervention of ganglia or of the central organs, into relation with the other elementary parts of the organism. Sensations or impressions received at the peripheral terminations of afferent nerves are conveyed instantaneously to some nerve-ganglion, or to the spinal cord, or to the brain, or to all of them ; and then, reflected thence along the efferent nerves, certain responsive influences are transmitted which, according to their destinations, result in muscular movement or in glandular action. Thus the central organs are kept informed of what is going on throughout the organism. And thus (to omit all reference to their influence over the voluntary muscles), by acting on the walls of the heart and blood-vessels, they regulate the supply of blood to parts, and so control their nutrition and the activity of their special functions ; by acting on the walls of gland-ducts, they modify the rate of escape of the products of the glands ; and by means of the trophic nerves (which many physiologists now believe to exist) they probably exert a direct influence over the action of the essential elements of secreting organs.

D. Ere we bring these preliminary physiological remarks to a conclusion, a more direct reference must be made than has hitherto been done to the fact that decay and death are essential elements in the normal processes of life. It has already been pointed out that every act of life is

attended with waste of tissue, and that living protoplasm is essentially unstable and short-lived. It must be added, that every part of the organism has a limited duration, which is far shorter than the normal duration of the body which it contributes to form, and that the parts are either removed by slow disintegration and degeneration or cast off in mass. We need only advert, in exemplification, to the shedding of the epidermis and of the elements of excretory glands, to the removal and re-formation of bone-tissue, to the generation and destruction of blood-corpuscles, to the atrophy of the uterus and the fatty degeneration of its muscular elements after parturition, and to the even more complete destruction, by similar processes, of the Wolffian bodies during foetal life, and of the thymus gland during the first few years of extra-uterine existence. Lastly, it must never be forgotten that atrophy and degeneration of organs and tissues are normal physiological processes of old age, and that somatic death, in which they culminate, is their normal termination.

---

#### IV. PHYSIOLOGICAL PROCESSES IN DISEASE

If we carefully consider the intimate processes of disease, we cannot fail to recognise the fact that they consist essentially in nutritive modifications of the protoplasmic or vital elements of the tissues; that under the influence of abnormal or unwonted stimuli (including the stimulus of excessive nourishment), these enlarge, multiply, or differentiate; that when insufficiently stimulated or fed or acted on by destructive agents, they undergo atrophy or degeneration, or perish; and that, as a necessary consequence of such changes, their functional attributes become heightened, or impaired, or more or less profoundly modified. Thus, on the one hand, we get simple hypertrophy, inflammation, or heterologous growth, and, on the other hand, fatty or calcareous conversion, or other forms of degeneration; and, again, functional derangements too numerous to mention, which constitute so large a proportion of the symptoms of disease.

But when we look to the marvellous complexity of the organism, to the intimate anatomical relations which subsist between the vascular and the nervous and other subordinate systems and organs, and to the correlation and mutual dependence of the various functions which all these different component parts of the organism are called upon to perform; and consider that the healthy structure and function of each are involved in a greater or less degree in the similar integrity of every other; we must admit (what the slightest practical experience will confirm) that we cannot limit our view of morbid processes to these intimate changes alone, but must embrace within it the structural and other modifications of organs to which such changes give rise, as well as those further nutritive and functional disturbances which, in a variety of ways (mechanical, chemical, and other), disease of one part necessarily evokes in a greater or less degree in all other parts of the system. We proceed to discuss at length the several matters here adverted to.

## A. MORBID GROWTH

1. *General Observations*

*a. Growth and development of cells.*—Whenever the protoplasmic particles or cell-elements of a part are stimulated to unwonted growth, they first increase in bulk, and become turbid, or minutely and indistinctly granular, and if stellate, fusiform, or caudate, at the same time retract their processes, and assume a more uniformly rounded shape; and then, by gemmation or fission, each cell gives origin to two or more smaller cells, which in their turn repeat more or less accurately the processes of growth and proliferation. The results of such stimulation, so far as regards the cells themselves, are, that sometimes the newly generated cells acquire in all respects the same characters as had formerly belonged to their immediate ancestors, that sometimes they retain permanently the immature or embryonic condition which represents the early or indifferent stage of nearly all cell-growth, and that sometimes again they undergo development into cellular bodies which differ materially in size, form, and attributes, from those which gave them origin. Simple hypertrophy or hyperplasia furnishes an example of the first of these alternatives, inflammatory cell-production of the second, and heterologous tumours of the last.

*b. Conditions associated with overgrowth.*—But where there is exaggeration of cell-growth, there necessarily is also at least proportionate exaggeration of the various conditions which are subsidiary to such growth—namely, exaggerated afflux of blood, exaggerated accumulation of nutrient fluid, exaggerated molecular destruction, and exaggerated efflux of superabundant and effete materials.

Increased afflux of blood is determined mainly by reflex dilatation of the arteries, capillaries, and veins, which minister to the needs of the affected part, and in a subordinate degree by increased force and frequency of the heart's contractions, and produces one form of what is known as 'congestion.'

Increased accumulation of nutrient fluid in the extravascular tissues is due to the preternaturally abundant escape of it from the dilated capillaries: an escape dependent in some degree on the vital influence exerted by the protoplasm of the capillary walls, and by the overgrowing protoplasm external to them. The tissues consequently get swollen, soft, and juicy, and in a greater or less degree 'dropsical.'

All vital activity, whether this manifests itself by material changes or by functional excitement, is attended with molecular disintegration, which has some exact quantitative relation with it; and hence increased vehemence of growth, and of reproduction, is necessarily accompanied with a proportionately increased production of effete and excrementitious matters. But, in addition, undue rapidity of cell-growth and development always involves a corresponding tendency to fall into premature decay and dissolution; and hence arise fatty and other forms of degeneration, the

products of which accumulate, and mingle with those of molecular disintegration. It is thus that the fluids of the affected region tend to become surcharged with innutritious, waste, and often noxious materials.

The increased absorption which takes place is probably dependent, in some measure, on the more active passage of fluid by endosmosis through the walls of the venous radicles, but is certainly due mainly to the more direct action of the lymphatic vessels. Indeed, it is almost impossible to suppose that those slightly diffusible substances, albumen and fibrinogen, should, in the face of the opposing pressure from within the blood-vessels, be capable of re-entering them, or that solid particles, whether indifferent or specialised, should be removable by any other route than that furnished by the open mouths of the lymphatics. And that these really are the main agents in the removal of probably everything, save a variable proportion of water and dissolved salts, is shown by the tendency which, when largely overworked, they and the glands in their course have to become enlarged and presently inflamed, or involved in the identical processes going on at the seat of absorption.

*c. Migration of leucocytes.*—One of the most interesting phenomena connected with the subject of local proliferation is the fact, stated many years ago by Dr. Addison, and since then clearly established by the experiments of Cohnheim and the later observations of many other physiologists, that in artificially produced irritation or inflammation of the tissues of the frog or mouse, after retardation of the current of blood in the vessels of the part has taken place, the white corpuscles gradually penetrate the vascular walls, and presently pass completely through into the tissues external to them. It has further been shown that these emigrant corpuscles take an active personal part in the proliferation which ensues; that is to say, that they then, as well as (if not more than) the proper protoplasmic masses of the part, give origin by gemmation or fission to new generations of cells. How far this process may be regarded as an essential element in the development of non-inflammatory growths, is at present in great measure a matter of inference. Still there are many good grounds for regarding it as an important item in all cases of abnormal cell-proliferation. And it is far from unlikely that it may be equally importantly concerned in the normal processes of growth and development.

*d. Tendency of morbid growth to spread locally.*—Morbid cell-development, occurring primarily at any one spot, generally has a tendency to spread in the neighbourhood of that spot. The direction of local spread is in most cases largely determined by the structure and connections of the tissue or organ in which the growth has originated. Thus, growths beginning in the cutis or mucous membrane are prone to limit their extension to these structures; and the same rule applies to the kidney, ovary, and other organs. Nevertheless, in many cases the morbid process tends gradually to involve all adjoining parts. This local spread is sometimes effected by the progressive involvement of the healthy tissues immediately surrounding the focus of disease; and very often partly by

this process, but partly also by the appearance of new foci of disease in the vicinity of the primary focus, and by their gradual coalescence with it and with one another. It is sometimes determined by the lines of capillary lymphatics and blood-vessels.

*e. Tendency of morbid growth to become generalised.*—The tendency to the simultaneous or consecutive occurrence of the same kind of morbid proliferation in different, and even remote, parts of the organism is traceable to a variety of causes, presents obvious and characteristic differences, and has therefore a widely different significance in different cases. The matter is one which deserves, and indeed demands, consideration; and we proceed, therefore, to discuss it in some detail. A person in apparently the best of health finds that he has a fibrous or fatty tumour in the subcutaneous connective tissue, or an osseous or cartilaginous tumour growing from the shaft of some bone; and probably in a short time it is ascertained that many other tumours, identical in character with the one first detected, are making their appearance in the connective tissue or the bones (as the case may be) of different parts of the body. Now it is indubitable that we have here a curious tendency in certain tissues of the body to undergo special morbid changes. To what is this tendency due? The first-formed tumour may be distinctly traceable to some local injury; has the growth which resulted from that injury so infected the system as to have led to the multiple development of similar growths throughout the same tissue as that which was primarily involved? Or have all the tumours (including the first) resulted from the common operation of some independent morbid irritant or poison diffused generally throughout the system? Or is there some inherent weakness or vice in the particular tissue, which has become thus largely affected, rendering it liable to take on specific morbid proliferation under the influence of mechanical violence or any other indifferent cause? In the examples which have been adduced (and many similar ones might be added), the last of the three suggested explanations will doubtless be regarded as the only tenable one; and probably it is the correct one. At all events, we have no grounds for assuming, from the presence of cachexia or other associated abnormal conditions, that any poisonous matter either is or has been present in the system; or, from the presence of lymphatic implication, that the primary seat of disease was the source of infection.

The case, however, is not quite so simple as it appears to be at first sight. The skin, like the bones or connective tissue, constitutes a special constituent of the organism, and like them (though in a still higher degree) is liable to many morbid conditions which are peculiar to itself, and which may be distributed at intervals over its surface. A patient may have psoriasis, beginning perhaps in a patch on the elbow or knee, and diffusing itself in spots over the greater part of the body. His father may have suffered from the same disease, and his brothers and sisters also may be subject to it. The case is one of hereditary predisposition. Now, probably no one would dream of suggesting that the spread of the disease was due here to the infecting influence of the patch which first

appeared on the knee or elbow ; and certainly no direct evidence could be adduced in favour of its dependence on any morbid irritant carried by the blood. The case would doubtless be regarded as equivalent, in point of origin, to that of multiple fibrous tumours or exostoses. But another patient has psoriasis differing a little in details of distribution and colour, but (unless we go into the previous history and subsequent progress of the case) probably in no other respect, from that observed in the former patient ; and further, at the time of observation he may in every other sense be perfectly healthy. He had a chancre, however, some time previously, and his skin-disease is due to the syphilitic poison. Or, to take another example, an apparently healthy person becomes liable, without obvious cause, to urticaria, and suffers from it off and on for years, perhaps for the remainder of his life. It is little, if at all, influenced by diet or habits and altogether uncontrollable by medicinal treatment, and moreover may be readily induced by a pinch or a scratch. There seems no reason to regard this, any more than simple psoriasis, as the result of a specific irritant working from within. But another person takes a meal of mussels and presently presents, together with more or less violent constitutional disturbance, an abundant urticarial eruption. Now here the relation between cause and effect is as obvious as in the case of syphilitic psoriasis. We have, thus, clear evidence that both psoriasis and urticaria are producible by the local operation of special poisons, which have been introduced from without, and have infected the system, and that the former may appear without necessary contemporaneous manifestation of other symptoms of disease. But do not these facts throw doubt on the non-specific origin of so-called 'idiopathic' psoriasis and urticaria, and hence also on the assumed non-specific causation of fibroma, exostosis, and the like ?

Nevertheless, while many specific affections of particular tissues are certainly traceable to the influence of specific irritants, it seems not improbable that other such affections are due simply to the influence of indifferent causes acting on parts which have acquired a special aptitude to take on such morbid action. At the same time it must be admitted that the absence of collateral evidence of the presence of systemic poisoning by no means proves the absence of such poisoning ; and, further, that the apparent commencement of the above or any like lesions from injury does not make it certain that this injury was its essential cause.

The difficulties which have just been briefly considered are equally apparent in the case of carcinoma and other infecting tumours. These, like exostoses and fibromata, become multiplied throughout the organism, and like them repeat in each newly formed growth the characteristics of the growth which was first developed. But they differ from them essentially in being heterologous in structure from the tissues wherein they first make their appearance, and because they are not, or not so obviously, limited in their further distribution to one special form of tissue. They differ from them also in the fact that, however we may explain their origin, the first-formed mass inoculates the system with the disease, as

truly as the inserted variolous contagium inoculates a person with small-pox, and exactly in the same way as a chancre infects its subject with constitutional syphilis. Thus, if a carcinomatous tumour makes its appearance in the testicle, the patient for a time seems, and probably is, free from disease elsewhere; but presently other organs get implicated, and in a certain sequence. First, the lymphatic glands, into which the testicular lymphatics run, become involved—these are the lumbar glands; and then, after an interval, the disease appears simultaneously in many tissues and organs. If a patient has carcinoma of the glans penis, the next manifestation of the disease occurs exactly where the effects of syphilis first reveal themselves, subsequently to a chancre of the same part, namely in the inguinal glands. And in this case, again, at a later period the disease becomes generalised. The same rule applies equally to cancer of the breast, uterus, or pylorus, and indeed to any primary cancer, no matter what its seat: first, the lymphatic glands in the neighbourhood, and especially those which lie in the direct route between the tumour and the thoracic duct, suffer; and, later on, patches of carcinoma appear, distributed throughout the organism. In diseases of this kind, every secondary tumour is equally infective with that which was first developed; and consequently, just as the primary tumour causes disease in the lymphatic glands related by position to its seat, so each secondary tumour tends sooner or later to infect those lymphatic glands which are in immediate connection with it.

*f. Tendency of certain morbid growths to limit their distribution to certain tissues or organs.*—But although carcinomatous tumours, and such growths as are related to them by their mode of dissemination from a primary focus of disease, undoubtedly tend, when they become generalised, to involve a much wider range of tissues and organs than do fatty tumours, exostoses, and the like, it is nevertheless certain that they have preferences or elective affinities, and that these are in some degree characteristic for each species of tumour; and further, as Virchow distinctly points out, the parts in which such affections usually originate are especially the parts which their secondary manifestations seem to avoid, and conversely. Thus tubercle and carcinoma, although severally disposed to involve secondarily a large number of organs, and many of them in common, present obvious peculiarities of distribution; for while both of them are specially apt to attack the lungs, brain, and serous membranes, carcinoma is yet more disposed to attack the liver, which tubercle generally avoids, and tubercle has a marked affinity for the mucous membrane of the bowels and for the spleen, in both of which situations secondary cancer is certainly rare. And thus, again, while primary carcinoma is common in the breast, womb, and alimentary canal, these parts rarely get involved when carcinoma originates in some other part of the system. The cause of the apparent capriciousness of distribution of secondary growths is very obscure. It is of course easy to understand why the lungs, which form a kind of filter to the universal blood, should be peculiarly liable to them; and why organs, such as the liver and kidneys, which

receive a specially copious supply of blood, or have such arrangements of vessels as retard or lengthen its passage through them, should be affected more frequently than others. But neither such conditions, nor others connected with the relative functional activity of organs, influential though they be, are alone sufficient to explain the phenomenon. It has recently been ascertained that lymphatic tissue is very abundantly distributed throughout the organism; and there is some reason to believe that the generalisation of both tubercle and lympho-sarcoma is connected with this fact, and depends either on some special proclivity to morbid processes which this tissue acquires under certain constitutional conditions, or else on the circumstance that it is the appropriate soil for the germination of the seeds of lympho-sarcoma and of tubercle. The latter is probably the correct explanation; and indeed, probably also in other cases, apparent capriciousness is mainly dependent on the special suitability of different tissues and organs for the reception and growth of different specific morbid elements—an explanation which is in entire accordance with all we know of the behaviour of the contagia of the exanthemata, of animal and vegetable parasites, and of other organic and inorganic poisons admitted into the organism.

*g. Connection of dyscrasia with the origin of morbid growths.*—Nothing which has yet been said relates in any degree to the question of the primary origin of infecting growths; it has simply been shown that when once developed they become sources of specific infection to their unfortunate possessors. This primary origin is referred by many persons to a ‘dyscrasia’ or morbid condition of system, itself supposed to be produced by the presence of some morbid matter or influence residing in the blood; and indeed Mr. Simon, who formerly adopted this view, regarded a carcinomatous tumour as a newly developed organ, whose express purpose was to effect the separation of such poison from the organism. There are several considerations which lend countenance to this hypothesis:—when a person exposed to atmospheric changes contracts pneumonia or any other variety of internal inflammation, an interval elapses between his exposure and the commencement of the inflammation, during which some abnormal condition of the system (a dyscrasia) is present; so again the incubative stage of small-pox or measles is a period of specific dyscrasia; and further, at any rate as regards tuberculosis, we know that it is apt to come on in individuals who have fallen into general ill-health. But, on the other hand, these examples are none of them strictly analogous to that of carcinoma; and one indeed (that of the exanthem) fairly considered tells the opposite way, for its incubative period corresponds, not to the supposed incubative stage of carcinoma, but to the period which elapses between the first appearance of a tumour and its generalisation. Besides in the great majority of cases in which we have the opportunity of observing the first manifestations of carcinoma, these are certainly not preceded by any evidence of ill-health; and, moreover, no such evidence becomes apparent until the patient is obviously beginning to suffer, directly or indirectly, from the effects of his disease.

The existence, then, of initial carcinomatous and other such specific dyscrasiæ may fairly be denied ; at all events, the only proof of their existence is the appearance of those very lesions which are attributed to their influence. And hence the only sense in which such a dyscrasia can be conceded is the sense in which we should admit a preliminary dyscrasia as the source of enchondromata, exostoses, fibrous tumours, leprous patches, and the like : a dyscrasia, that is to say, of limited distribution, and consisting simply in a tendency (congenital or acquired) in certain parts of the body to undergo a special kind of proliferation under the operation of various forms of irritation. It need not of course be denied in this case, any more than in that of non-infective growths, that such a tendency may exist simultaneously in various parts of the body ; and that hence, although it is certainly not the rule, there may be a concurrent primary outbreak of infective growths in two or more localities.

*h. Secondary dyscrasia.*—But although a state of cachexia, or a dyscrasia, is not an essential antecedent of primary infective growths, there is no doubt that a condition of cachexia speedily follows upon their appearance. The fact has already been adverted to that, from any focus of morbid proliferation, there is an abnormally large reflux of nutrient fluid into the general circulation, partly by the veins directly, but chiefly by the lymphatics, and that this nutrient excess is largely charged with effete and morbid products, generated in the diseased area. These products comprise : the ordinary waste-materials, such as carbonic acid and urea ; materials which are traceable to the special chemical constituents of the part involved—earthy matter if it be bone, phosphates if it be brain ; and probably also fibrine or fibrine-producing substance, which, as Virchow suggests, is manufactured at the seat of disease, and being removed thence by the lymphatics, overcharges the blood and gives it its inflammatory character. But, in addition, specific affections yield specific elements, which also traverse the lymphatics, and presently mingle with the blood. What these are is not accurately known ; but probably (judging from the analogies afforded by the infectious fevers) they are living protoplasmic particles evolved by the primary growing mass, which get arrested in the lymphatic glands and then infect them, by either growing parasitically among their elements, or (sperm-like) imparting to them specific properties ; and which presently are shed thence in new generations, through the thoracic duct into the blood-stream, to sow themselves in distant organs. Now, in all these processes, it is obvious that we have ample sources of deterioration of the general health, and of functional disturbance of various parts of the organism—in other words, of a secondary dyscrasia. But it is obvious, also, that the degree and character of the dyscrasia will vary according to the peculiarities of the morbid process to which it is due, and especially that that accompanying the development of infective growths will be attended with specific characteristics. Further, more or less in most cases, but in the last more particularly, dyscrasia will probably be largely increased, by the constant drain of nutriment which the growth and ulceration of tumours necessarily involve, and by

the obstacles which, by pressure or otherwise, these so often interpose to the due performance of important or necessary functions.

When secondary dyscrasæ are present we often find that some mechanical injury, or the result of some such injury, attracts, as it were, specific morbid processes. When, for example, a patient is suffering from constitutional syphilis, a local outbreak is often thus determined. It is probable that this phenomenon is due to the fact that parts, in which certain non-specific morbid processes are in progress, furnish a specially suitable soil for the growth and development of specific elements of disease, which happen to be circulating in the blood. The interesting experiments of Chauveau seem strongly to confirm this view. He found that, on injecting putrid fluids containing bacteria into the blood of healthy animals, no special consequences beyond some constitutional disturbance necessarily followed; but that if, after injecting them, the operation of twisting, and thus strangulating, one testicle was performed (an operation common in France and leading to the general wasting of the organ), violent inflammation with sloughing, probably attributable to an abundant development of bacteria, took place in the injured part, the opposite uninjured testicle remaining altogether unaffected.

*i. Meaning of terms malignant and innocent.*—It may be well here briefly to explain the meaning of the terms ‘innocent’ and ‘malignant,’ as applied to morbid growths. Malignant is almost synonymous with infecting; but not quite—for a chancre and an inoculated variolous pustule are both infecting growths, yet not malignant. The word implies, therefore, something more than is presented by either of these affections. It implies, in fact, additionally, that the morbid process going on in any one locality has a tendency to invade all the tissues which are round about it, and none whatever towards cure, or even to remain quiescent. A malignant tumour may, therefore, be defined as one which tends to involve all surrounding structures, and to disseminate itself through the agency of the lymphatics and veins, and has no disposition to spontaneous cure. The term ‘innocent’ is mostly understood to signify simply that a tumour is non-infective. Malignant tumours often present other characters which, though not necessarily associated with malignancy, are yet highly suggestive: these are, aptitude to recur after removal, abundance and rapidity of cell-growth, softness and juiciness of tissue (the juice being milky), great vascularity, and marked differences of texture as compared with that of the parts in which they originate.

A very characteristic feature of most morbid proliferations, whether they be malignant or innocent, is their quasi-parasitic nature: their disposition to grow and maintain themselves, independently of the general health of the body in which they are developed and from which they derive their sustenance. Thus, a large abscess, so far from becoming starved by the gradual emaciation of its possessor, will often go on increasing even more rapidly as his body dwindles away. And so also, enchondromatous, fatty, and carcinomatous tumours, and tubercle, show no signs of impaired vigour of growth, even while the patient is progres-

sively wasting under their influence. Over-nutrition and under-nutrition of the body of their host are alike without obvious influence over their progress.

*k. Relation between infective morbid growths and specific febrile diseases.*—It is impossible to overlook here the close relation there seems to be between malignant tumours on the one hand and at any rate certain of the specific communicable diseases on the other. We have shown that if a malignant tumour appear at any one spot, as a general rule the lymphatic glands in immediate relation with it before long become involved, and subsequently tumours resembling the first arise simultaneously or in rapid succession in various other parts of the system. Syphilis and small-pox (which may be taken as types of the specific communicable diseases) are characterised by the same sequence of events. If either of these be imparted by inoculation, a specific infective growth takes place at the point of operation; then, after a definite period, specific implication of the neighbouring lymphatic glands ensues, and concurrently or a little later the poison disseminated throughout the system gives origin to a more or less widely distributed outbreak of lesions specifically identical with that from which they took their origin. Further, in these and such like affections, there is (as is also observed in malignant diseases) a tendency for each kind in its secondary manifestations to implicate certain tissues and organs in greater degree than others. Tuberculosis has, both in structure and in behaviour, a close affinity with syphilis. Now, as we have already hinted and shall hereafter explain at some length, there are overwhelming reasons for regarding the specific causes of small-pox, syphilis, and all other specific communicable diseases as lowly vegetable organisms; and it has recently been (apparently) proved that tubercle itself, which had hitherto been regarded as a quasi-malignant tumour, is also the product of a specific vegetable parasite. Should this view of the causation of tubercle stand the test of experience, it will be difficult not to anticipate that sooner or later a like origin will be discovered for all infective growths, and even for many growths which are usually regarded an innocent.

## 2. *Hypertrophy. Hyperplasia.*

The term ‘hypertrophy’ is commonly used somewhat loosely of all organs or tissues which, from no matter what cause, have undergone abnormal increase of bulk. Thus, a liver enlarged by fatty deposit or lardaceous infiltration is often said to be hypertrophied, as also is an ordinary swelled testicle or a lymphatic gland affected with tubercle or carcinoma. But in such cases as these the enlargement is due essentially to the deposit of some extraneous matter, or the development of some inflammatory or other morbid growth; and the normal structure of the organ, so far from being increased in quantity or size, has probably undergone atrophy or degeneration.

True hypertrophy of an organ consists, either in an enlargement of its essential elements, or in an increase in their number. By Virchow

the latter variety of over-growth has been distinguished as 'hyperplasia.' The former process is exemplified by the enormous enlargement of the unstriated muscular fibres of the womb which takes place during the progress of pregnancy; the latter by the overgrowth of bone, which is effected simply by the multiplication of its elementary parts. It is very difficult, however, in many cases to determine positively by which of these two processes an overgrown organ has become enlarged, and doubtless they frequently co-operate.

Of all morbid processes, simple hypertrophy seems to approach nearest to the processes of health; indeed it is mostly due to the operation of the very causes which produce normal increase of bulk, and in a very large number of cases is, for a time at least, protective or otherwise beneficial. Thus, one can scarcely draw the line between that normal growth of the heart, which comes with advancing years and activity of body, and that excess of enlargement which sustained and over-violent exertion brings about, and which presently reacts injuriously; and it is hard to admit that that hypertrophy of the heart's walls which follows naturally on obstructive disease at the cardiac orifices, and tends to counteract its ill-effects, is truly morbid. Similar hypertrophies of the muscular parietes of the hollow viscera are always apt to arise under circumstances which compel them to long-continued unwonted action. We may refer to the hypertrophy of the stomach which occurs when the pylorus is diseased, to that of the intestine in cases of intestinal obstruction, and to that of the bladder, ureter, or other reservoir or duct when some mechanical impediment prevents the due escape of its accumulated contents. Such consecutive, and often beneficial, hypertrophies are not confined to muscular organs, but may occur in glands, in bones, and elsewhere:—in the kidney, for example, when in consequence of the destruction of one its fellow attains unwonted dimensions, or when both undergo enlargement under the influence of diabetes; in the bones, as when a protective buttress is formed in the concavity of a curved rickety tibia.

Not all forms of hypertrophy, however, are a consequence of the attempts of organs to adapt themselves to conditions of increased work. Hypertrophies which are essentially abnormal, and have no beneficial tendency whatever, arise in some cases from the direct influence of the nervous system; in others (and these are the most frequent) from the stimulus of excessive supply of nourishment. Amongst the former may be included the hypertrophy of the heart which long-continued nervous palpitation induces, and that form of goitre which occurs in 'Graves's' disease; amongst the latter, that general enlargement of the lower extremity (in which the bones get longer and thicker than those of its fellow, and the other structures of the limb proportionately increased) met with in cases where, owing to obstruction and dilatation of its lymphatics, the whole member is succulent with nutritious fluid. A particular form of hypertrophy of the tongue in children, and the over-growth of the skin and subcutaneous connective tissue in elephantiasis, also are largely due to this last condition.

Occasionally, owing doubtless to some congenital proclivity, some one part of the body, as, for example, an arm or leg, grows during childhood in all its dimensions disproportionately to the rest of the frame, and while retaining its healthy structure attains relatively gigantic proportions.

### 3. *Inflammation*

*General account.*—The collective morbid phenomena which are included under this term occur as an essential, or as an accessory, part of the great majority of diseases. They represent the reaction of the system, or of parts of it, against the injurious effects of irritants which are morbid either from their amount or from their quality; the efforts by which nature endeavours to destroy, counteract, or throw out what is noxious; and those by which she strives to repair what has been injured, and to restore what has been destroyed. It need scarcely be added that inflammation often goes far beyond, or falls far short of, its aim, and often acts as it were capriciously and blindly.

The classical local signs of inflammation are *redness, swelling, heat, and pain*. These no doubt are all present in the majority of cases; the redness being due to accumulation of blood in the dilated blood-vessels; the swelling, partly to this dilatation, partly to simple effusion and growth of tissue; the heat, in some degree to the increased afflux of blood, in some degree to the rapid disintegration that is in progress; and the pain, to pressure on the sensory nerves, or to their implication in the morbid processes. But neither redness, swelling, heat, nor pain is absolutely essential to inflammation: they are simply to be regarded as common results or accompaniments of that process.

Inflammation consists primarily and essentially in an unnatural irritability, and tendency to undue proliferation, of the protoplasmic elements of a part: these giving rise, not as in simple hyperplasia to a mere increase in the number of the normal elements, but to cells which tend to resemble leucocytes, or embryonic cells, and which never go beyond the formation of simple granulation-tissue, or some variety or modification of the various forms of connective-tissue. The connective-tissue corpuscles are those in which inflammatory proliferation chiefly takes place; but all protoplasmic masses, including those of the epithelia, those connected with the nerves and striped muscles, and also those which by their coalescence form the walls of capillary vessels, readily participate in the process. As doubtful exceptions may be named the special cells of the central nervous organs, the proper liver-cells, and other cells which have attained a high phase of development.<sup>1</sup> But in connection with these extra-vascular changes, vascular phenomena speedily ensue, and at once take an active share in the processes which are going on. Among the incidents which occur in the course of inflammation or

<sup>1</sup> It is not intended to suggest that these highly endowed cells are incapable of undergoing any form of inflammatory change, for observations by M. Charcot seem to prove that the proper cells of the nervous centres may be the primary and chief seats

follow upon it are, exudation, suppuration, ulceration, gangrene, and granulation or repair.

*a. Extra-vascular processes.*—The extra-vascular processes of inflammation may be best observed (observed freest from complication) in parts devoid of vessels, such as the cornea, cartilage, and certain portions of the mesentery. If a costal or articular cartilage be excited to inflammation by the mechanical removal of a bit of it, the injured surface becomes covered at the end of about a week with a soft, greyish pulp, which consists entirely of embryonic tissue, or a mass of embryonic cells together with some newly formed blood-

vessels. If now a cross-section of the cartilage be made so as to include its whole thickness, together with the wounded surface and the pulp covering it, the following appearances will be detected on microscopic examination in successive order from the region furthest

FIG. 1. INFLAMMATION OF CARTILAGE.  $\times 250$ .  
(Cornil and Ranvier.)

removed from the seat of injury to the surface:—first, the cartilage-cells and the hyaline intervening substance in a perfectly normal condition; second, simple enlargement of the cells and of their nuclei, and of the cavities in which the cells are contained; third, fissiparous multiplication of the enlarged cells and nuclei, and the appearance therefore of several closely packed nucleated cells in each originally unicellular cavity (each young cell, moreover, being invested in a thin cartilaginous capsule, and so still presenting the essential characters of a cartilage-cell); fourth, continued proliferation (the cells becoming smaller and much more numerous, losing their cartilaginous capsules, and assuming all the characters of simple embryonic cells, and the cavities containing each group of embryonic cells still enlarging at the expense of the hyaline cartilaginous substance, and hence approaching one another and here and there coalescing); fifth, an irregularly scalloped border, to the whole surface of which is attached, and from the whole surface of which grows, the grey film of embryonic tissue covering the injured surface of the cartilage (each scallop representing a portion of a primitive cartilaginous capsule, the cavity of which has come to blend with those around it, and the continuous embryonic mass representing the united proliferating contents of these and other lost cartilage-capsules). We thus see the effects of injury to be: first, growth and proliferation of the protoplasmic or living parts of the cartilage (the newly formed cells gradually losing the anatomical and other attributes of cartilage-cells, and degrading

of such changes; still less that they take no active part in non-inflammatory morbid growth, for the investigations of Dr. Creighton tend to show that heterologous growths in the liver commence with vacuolation and internal gemmation of the proper liver-cells.

into simple embryonic cells); and, second, progressive deliquescence and removal of the hyaline or non-vital constituent of the cartilage under the influence of this cell-growth and multiplication, culminating in its entire disappearance from those parts in which proliferation has attained its most advanced stage.

The mesentery of the adult animal forms, not a uniform lamina, but a delicate network, of which the trabeculæ are in many cases exceedingly fine, without blood-vessels, and consisting solely of a core of connective tissue, and an investing layer of polygonal tessellated epithelium. If a little solution of nitrate of silver be injected into the peritoneal cavity of such an animal, inflammatory changes take place in that epithelium, as they have just been shown to take place under analogous circumstances in the cells of cartilage. At the end of about twenty-four hours, turbid fluid is found in the serous cavity—the turbidity being due to the presence of cellular elements, presenting all varieties between ordinary pus-corpuscles on the one hand, and larger cells containing two or more oval well-defined nuclei on the other; and the epithelial cells at the surface of the

FIG. 2.—INFLAMMATION OF MESENTERY.  
×250. (Cornil and Ranvier.)

trabeculæ have become plumper and larger, have lost their cell-walls, and in many cases have undergone proliferation, giving rise to pus-cells and such other forms of cells as are found floating in the peritoneal fluid. The cells adhere irregularly to their points of origin, and are invested, and to some degree retained *in situ*, by bands of coagulated fibrine which has exuded from the inflamed surface. If no further irritation be excited, at the end of a few days the cells floating in the peritoneal fluid get opaque and fatty and perish, while those which are still adherent to the trabeculæ flatten and resume the ordinary characters of serous epithelium.

In the above two cases we have proliferation simply of the cells which are proper to the irritated tissues; in the case of the cornea, however, the results of irritation are more complex and remarkable. The cornea of the frog consists mainly of a network formed by the union of the rays of stellate cells—the meshes being occupied by indifferent non-vital material, which corresponds to the hyaline matrix of cartilage, and to the white fibrous trabeculæ of ordinary connective tissue. If the living cornea be irritated by the application of a point of nitrate of silver to its centre, changes presently take place in it, which soon spread, and before long involve the whole extent of its tissue, rendering it more or less obviously milky and opaque. The first changes discoverable by the microscope are in the immediate vicinity of the injured spot. Here the stellate cells first become unnaturally well-defined, and a little more granular or turbid than in health; then they swell, their branching processes at the

same time growing thinner; presently these are retracted, and the still-growing cells, assuming a somewhat nodulated or botryoidal form, become as isolated from one another in the substance of the corneal matrix as are normally the cells of cartilage in the cartilaginous matrix. Whilst these changes are in progress the cells grow more and more opaque, and their contents more and more difficult to discriminate; but soon obvious proliferation occurs within them, the nuclei divide and subdivide (each division carrying with it its own particular envelope of protoplasm) until every corneal cell becomes the mother cell of an irregular group of embryonic corpuscles. This increase of the vital elements of the cornea is attended, as is the equivalent process in cartilage, by the liquefaction and removal of the intervening matrix, and ultimately by the coalescence of neighbouring groups of cells and their discharge from the surface of the organ. So far the process is essentially the same as in cartilage, and indeed as in serous membrane also. But something more occurs. Whilst the changes above described are going on in the centre of the cornea and gradually spreading from that point outwards, other changes are taking place at the periphery of the cornea and creeping thence in the centripetal direction. These consist in the gradual escape of leucocytes from the now dilated marginal vessels, and their immigration (in virtue of their amœboid properties) into the interstitial spaces of the adjoining parts of the cornea. These spaces they soon crowd, rendering the corneal tissue opaque; and soon breed, mingling their offspring with those of the proliferating corneal cells, from which they become undistinguishable. Cohnheim, who first recognised this immigration of leucocytes into the inflamed cornea, attributes all the morbid cell-development occurring in it to their presence and action, and considers that the proper corneal cells remain perfectly passive. The active share, however, which these latter take in the inflammatory process has been so often described by competent observers, that it is difficult not to believe in its truth, and if this be so the concurrence of these two processes, not only in inflammation of the cornea but in the inflammation of other parts, must be admitted.

Processes, essentially identical with the above, mark the occurrence of inflammation in the intervacular spaces of the so-called 'vascular' tissues:—they are, growth and multiplication of the protoplasmic elements; immigration and multiplication of leucocytes; and concurrently, the liquefaction or degeneration, and disappearance, of the non-vital parts, and indeed of living parts which have attained their highest phase of development. Thus we find the earthy and organic matrix of bone eroded into cavities, the trabeculæ of white fibrous tissue attenuated into a comparatively delicate network, and muscular and nervous tissues undergoing fatty metamorphosis.

*b. Vascular processes.*—The condition of the blood-vessels in and about an inflamed part has long engaged the attention of pathologists. The important share which they take in inflammation is indicated by the redness which attends the process, and by the dilatation and throbbing of

the arteries which lead to the spot in which it is going on. The latter fact indeed sustained, if it did not originate, the belief that the increased flow of blood to an inflamed part was determined by the active movements of the vessels of the part, in the same way that the general distribution of the blood is governed by the alternate contractions and dilatations of the heart.

That the active processes going on outside the vessels in an inflamed area create a demand for an increased supply of nourishment, has already been pointed out. This demand can only be satisfied through the medium of its blood-vessels, which consequently soon dilate, and thus attract thither an excessive amount of blood. This phenomenon, indeed, so speedily follows the event which calls it into operation, that in inflammation produced experimentally it is often the very first indication of the presence of inflammation. If the web of a frog's foot, or its mesentery, or any other convenient tissue of one of the lower animals, be irritated and the processes which follow carefully observed, it will be seen : that the small arteries of the irritated area gradually dilate and probably after some hours attain their maximum diameter, which may be double that originally presented by them ; that, subsequently to the commencement of the arterial dilatation, perhaps some hours afterwards, the capillaries and veins of the part follow suit, and that thus at length all its vessels get proportionately enlarged. It will further be seen that, while these changes of dimension are going on in the vessels, equally remarkable changes are occurring in the blood-stream within them : at first, while only the arteries are affected, the rate of flow is increased ; then as general dilatation of the vessels supervenes, the stream flows more and more slowly through them (oscillating, perhaps, in some of the capillaries), and the white corpuscles congregate and cling to the vascular walls ; at length the blood stagnates, and loses its serum, and the red and white corpuscles get wedged together into an apparently homogeneous or amorphous mass. While, however, this condition of stasis has been coming on in the area of inflammation, the vessels immediately around it have become dilated, and through them the blood is still circulating with unwonted rapidity.

It is at the period of stasis, or rather perhaps just previous to it (at the time when the white corpuscles or leucocytes are adhering in large numbers to the inner surface of the vessels), that that emigration of corpuscles which has already been adverted to, and plays so important a part in the inflammatory process, chiefly occurs, and may be best observed. If at this time the small veins be narrowly watched (for it is in them that the process commences, and chiefly to them that it is confined), small, transparent, button-like bodies will be seen to spring here and there

FIG. 3.—MIGRATION OF WHITE CORPUSCLES.  $\times 250$ .  
(Rindfleisch.)

from their outer surface ; these gradually increase in bulk and number, and assume a pyriform shape, and presently, having acquired the form and

size of white corpuscles, detach themselves from the surface from which they seemed to grow—their connection therewith having previously been reduced to a mere thread. Prior to their complete detachment they often throw out delicate processes which aid them in their ulterior movements. In this way vast numbers of white corpuscles pass in a short time from the interior of the vessels into the tissues external to them, without leaving behind them a trace of the route by which their escape through the parietes was effected.

It is obvious, then, that variations in the dimensions of vessels, and in the rate of flow of blood through them, are very important incidents in the collective phenomena of inflammation. But it is not at all easy to determine upon what cause, or on what combination of causes, the several variations depend; and especially it is difficult to trace the exact relation between the varying diameters of vessels and the varying rates of the passage of their contents along them. We know that the smaller veins, and still more the smaller arteries, are capable of contracting and dilating within comparatively wide limits, and thus of regulating to a considerable extent the amount of blood to be admitted into, or discharged from, the area to which they minister; and that this function is effected by means of their muscular walls, which, when they contract, diminish the calibre of the vessels, when they relax, permit of their dilatation. We now know also, chiefly through the labours of Stricker, that the capillary vessels are not merely passive organs, contracting and dilating in obedience to the various degrees of blood-pressure to which they are subjected; but that, in virtue of the endowments of the living protoplasm of their walls, they possess, like the arteries and veins, a power of active contraction. And, further, we now have good reason to believe that arteries, veins, and capillaries possess, in addition to the power of active contraction and the capability of passive dilatation, a distinct power of active dilatation, or at any rate of dilatation with retention of tonicity. Again, we know that the muscular tissue of the vascular system, like that of all other parts, is under the dominance of nerves—in this case the nerves of the vaso-motor system. Contraction of vessels may be caused, either by the direct application of irritants to them, or by exciting the cut surface of the distal portion of a divided motor nerve, comprising vaso-motor fibres, distributed to them. Active or tonic dilatation seems specially to be induced either by direct irritation of the dilator nerves or by reflex action, excited by stimulating the sensory nerves of the part in or near which the vessels undergoing dilatation are situated. Passive dilatation takes place whenever the influence of the vaso-motor nerves is abolished or weakened, or the vascular walls lose their proper contractile power. We may gather from this statement that the primary dilatation of the vessels of inflamed parts is due to reflex stimulation, traceable to the inordinately active vital processes which are taking place in the extra-vascular tissues; and that the later dilatation is probably merely passive. As regards the question of the variations which take place in the rate of the blood-flow in the vessels of

inflamed parts, it will be sufficient for our purpose to point out: that the increase which occurs in the early stage of inflammation in the centre of the inflamed area, and which is maintained continuously in the immediate neighbourhood of the lesion, is in obvious accordance with the physiological fact that dilatation of the smaller vessels not only admits of a larger presence of blood in them, but allows of a more ready transit of blood through them; and that the stasis, which takes place after a time in the still dilated blood-vessels of the inflamed area, is obviously connected with the tendency which the corpuscular elements of the blood have then acquired to adhere to, and pass through, their walls—which conditions in their turn doubtless depend on the altered nutritive relations then subsisting between the walls of the vessels and tissues external to them on the one hand, and the blood within them on the other.

*c. Exudation.*—The abundant fluid which sweats from the vessels during inflammation, though consisting essentially of the serum of the

FIG. 4.—FIBRINOUS EXUDATION.

b. From inflamed pleura.  $\times 500$ .

blood, presents modifications of constitution determined by the tissues in connection with which its escape occurs, and further involves different results according to the circumstances attending its escape. The swelling, which always accompanies inflammatory processes going on in the substance of organs and tissues, is

mainly dependent on this exudation; and indeed, if the parts involved be lax, serous infiltration, or œdema, is apt to spread far beyond the limits of actual inflammation. In inflammation of mucous membranes, the membrane itself, and the tissues which are subjacent to it, all get infiltrated; but, in addition, there is generally a copious discharge of fluid from the free surface. The most abundant discharge, however, takes place into serous cavities when the membrane which invests them is the seat of inflammation. It is thus that hydrothorax and ascites are often produced. The most common distinction between inflammatory fluid-exudation and blood-serum is the presence in the former of a comparatively large quantity of fibrine, or fibrinogen. This is observed to a greater or less extent in all cases, but is especially remarkable in the inflammations of serous membranes, in which the great bulk of the exuded fibrine coagulates at the moment of its escape, entangling morphological elements, and forming the false membrane which adheres so characteristically to the surface. Another, but less frequent, peculiarity is the appearance in it of mucine; this is observed chiefly when the mucous and synovial membranes are affected, and is due to the direct influence of the cells of the diseased surface. We have pointed out that the exudation of white corpuscles is

probably an essential element in the inflammatory process; small but variable numbers of red corpuscles also are apt to exude in company with them; but at times the escape of blood-cells is much more abundant than can be explained by this process, and is manifestly due to actual rupture of blood-vessels—generally vessels of new formation.

*d. Suppuration.*—A frequent event of inflammation, and one that marks one of its recognised stages, is the formation of pus. ‘Laudable pus,’ as it is termed, is a thick, creamy, mawkish-smelling, alkaline fluid, containing a great abundance of corpuscles, to the presence of which its opacity and whiteness are due. The fluid part, which is called the ‘liquor puris,’ contains, like the serum of the blood (from which it is derived), albumen, salts, &c., and differs little from it in composition. It sometimes also presents a peculiar albuminoid substance, named ‘pyine.’ The corpuscular part consists almost entirely of bodies termed ‘pus-cells,’ which, as generally seen, are globular in form, varying between  $\frac{1}{2500}$  and  $\frac{1}{3000}$  inch in diameter, and differing little, if at all, from leucocytes, or so-called ‘mucous corpuscles,’ or embryonic cells. They are transparent, colourless, more or less granular masses of protoplasm, without investing membrane; which, though globular when dead or as usually examined, present active

FIG. 5. PUS-CELLS.  $\times 500$ .

amoeboid movements of locomotion and change of form, while still living and under appropriate circumstances. Under the influence of water, or still better dilute acetic acid, the general substance of each corpuscle swells up and increases in transparency, and one nucleus, or more frequently two, three, or more nuclei become revealed within it.

It is obvious, then, that there is little or no microscopical difference between typical pus-corpuscles and the corpuscles developed, previous to the suppurative stage, by the breeding of connective-tissue cells and other stationary protoplasmic bodies, or of immigrant leucocytes, and that they have both a common origin. Indeed at every suppurating surface the gradual transition of the one into the other may be readily observed. There is, however, some reason to doubt whether pus-corpuscles ever multiply, and some reason to believe that the groups of small nuclei they contain are to be regarded as the last abortive attempt at reproduction.

It is not difficult to trace some of the steps which lead to the development of pus. It has already been shown that when inflammatory proliferation is going on the indifferent or non-vital tissues between the groups of swarming cells gradually get eroded and removed; and that

presently, as these disappear, the neighbouring groups of cells come into direct relation with one another, and thus constitute an almost uniform mass of embryonic tissue. They still cohere, however, either as epithelial cells do, or through the intervention of some scanty adhesive material. It needs only the loss of this cohesive property, and the addition of the liquor puris, to convert this inflammatory hypertrophy of tissue into orthodox pus. It is thus, indeed, that suppuration takes place at the surface of an ulcer; it is thus, also, that abscesses arise. In the latter case: softening occurs in the centre of some proliferating region, and the cells, which would otherwise have formed an ingredient of solid living tissue, change into pus-corpuscles; by extension of the softening, the abscess enlarges, and more corpuscles are added to its contents; and further, the existence of a cavity induces towards it a rapid migration, both of the extravasated leucocytes and of the other embryonic cells which crowd the periphery. By continuance of the above processes, abscesses approach neighbouring surfaces, point, and presently rupture. The pus-corpuscles contained within abscess-cavities speedily undergo degenerative changes, and perish: they get studded with fatty particles, swell, and subsequently break up into a detritus; or they contract and become opaque and angular; or they undergo calcareous impregnation. And thus the contents of abscesses are gradually absorbed, or converted into caseous, mortary, or other such stuff, and a more or less perfect cure ensues.

Pus of recent formation does not always present the exact characters above assigned to it, but sometimes is thin and watery (*ichor*), sometimes contains a greater or less admixture of blood (*sanies*), and sometimes is distinctly fetid. These obvious peculiarities are dependent on something special, either in the condition of the patient or in that of the part which is suppurating, and are connected with peculiarities of microscopical and chemical constitution. Thus, we occasionally find that all the pus-corpuscles have already undergone degenerative change, and that in place of the orthodox cells we have only granule-cells, or it may be a mere molecular débris; or that abundant blood-corpuscles are mingled with the other elements of pus; or that fragments of tissue (bone, and the like) are contained in it; or that bacteria and other minute living organisms are present. The admixture of visible particles of tissue implies the association, with the suppuration, of somewhat rapid destruction of parts, and often indicates necrosis or gangrene; the presence of bacteria and the like is a proof, either that the pus is undergoing putrefaction, or that the blood generally is infected with them. Under these latter conditions fetor is pretty certain to be present.

*e. Destructive processes.*—The destructive effects of inflammation have already been adverted to. They are shown in the softening and disintegration which take place in the hyaline substance of cartilage, in the white fibrous element of connective tissue, and in the earthy matrix of bone, during the gradual multiplication of cellular elements, and especially during the formation of abscesses. They are shown also in the fatty and

other degenerative processes which, under similar circumstances, go on in muscle, nerve-cells, and other higher tissues, taking no part in the inflammatory proliferation. Destruction occurs, however, in a yet more marked form in the various processes termed 'ulceration' and 'necrosis' or 'gangrene.'

In *gangrene* a larger or smaller portion of tissue perishes, and is probably separated in mass from the neighbouring living textures. The death of the part is due essentially to its deprivation of nourishment; which deprivation depends mostly on obstruction of the arteries leading to it, either by clot in their interior, or by thickening of their walls, or by external pressure arising from accumulation of inflammatory products or other causes. In inflammatory gangrene the parts involved are usually swollen or succulent, for the reason mainly that, like all inflamed tissues, they were previously infiltrated with abundant exudation.

In *ulceration* the destruction of parts is molecular, or by small fragments, and progressive. It has long been a question whether, in the common forms of ulcer which gradually extend in area and depth, the apparent melting away of tissue, on which their extension depends, is due to absorption by the vessels or to discharge from the surface. It is obvious, in any case, that this gradual disappearance of tissue must be preceded by its liquefaction, degeneration, or death; for these are normal and necessary processes by which, even in health, the worn-out portions of the body are prepared for removal by absorption, and equally the processes by which, during inflammation unattended with ulceration, the more lowly-organised structures (the matrix of cartilage, cornea, bone, and the like) melt away and disappear; and indeed it is impossible to conceive of any other. Looking then to the fact that the molecular destruction, which is going on at the surface of ulcers, presents no real difference from that which is going on in the non-ulcerating stage of inflammation (the products of which are certainly removed in chief measure by absorption), it seems not improbable that a portion of the effete products of ulceration also may be removed in this way. But on the other hand, since the destruction takes place at a free surface, which is exuding a considerable quantity of fluid and even of corpuscular elements (conditions which are highly favourable for the discharge from that surface of any effete matters which are produced there), it seems hardly likely that these should be removed by absorption only. Indeed it seems most probable, on physical grounds alone, that the chief removal of ulcerative detritus should be effected in the manner last described. That it is mainly thus removed is now generally acknowledged. It may be added, in confirmation of this view, that the discharge from ulcers involving bone contains earthy matter, and even small fragments of bone; and that generally, when ulceration is extending rapidly, fragments of disintegrated tissue are suspended in the fluids which exude from the ulcerated surface. In sloughing ulcers, such as those attacked with hospital gangrene, extension is attended with an

abundant separation of shreds and flakes of dead tissue from the diseased surface.

It will of course be understood that the above remarks apply only to those cases in which ulceration is in progress. Excavations, whether termed ulcers or not, in which the surfaces are granulating, are examples, no longer of ulceration, but of repair and restoration.

*f. Organisation and granulation.*—It has already been shown that, at an earlier stage than that at which suppuration occurs, the results of inflammatory proliferation are the production of a greater or less quantity of embryonic tissue, or tissue at a low phase of organisation. If solid structures be implicated, the intervening matters melt away, and the newly formed cells come into near, if not absolute, relation with one another; if the process occur at the surface of a serous membrane, the new-formed cells are retained in connection with that surface by entanglement in the fibrine which coagulates there. In the progress of organisation important changes ensue. In the latter case the embryonic corpuscles, entangled in the fibrine, throw out delicate processes, by which they presently unite with one another to form a network, in the meshes of which the fibrine is then contained. At the same time, new vessels, starting from the normal vessels of the subjacent serous membrane, shoot into the adventitious tissue. Later, the fibrine undergoes liquefaction and removal, and the interspaces between the cells get occupied by a form of white fibrous tissue, which they are instrumental in manufacturing. In the case of the organisation of inflammatory products occupying the substance of organs, essentially the same series of events happens:—the embryonic cells undergo conversion into connective-tissue corpuscles; new vessels are formed; the fibrine which has coagulated, and in a greater or less degree the proper or special highly endowed elements of the parts, get removed, and the non-vital elements of connective tissue are deposited in their place. In both cases the new-formed tissue belongs to the connective-tissue series, and in both tends to contract and get dense and hard in texture.

The processes, here briefly described, take place also in the healing of wounds, and in the filling up of ulcerous or other excavations by granulation. Granulations are hemispherical masses of cells, produced and increasing in size by constant cell-breeding and immigration of leucocytes. The cells in the first instance are purely embryonic in character, and many of those growing at the free surface, and others which migrate thither, are shed as pus. But presently those which remain undergo differentiation; the majority elongate or send out processes and gradually evolve connective tissue; whilst others also elongate, but become aggregated into solid cylindrical loops, soon to be hollowed into channels of communication with previously existing vessels, and thus themselves to become blood-vessels, and important agents in the further growth and vitality of the granulation-tissue. Rindfleisch describes and figures the formation of lymphatic tissue in the overgrown vegetations of 'proud flesh.' Neighbouring granulations, as they grow, run together and blend,

and thus at length cavities get filled up with a tolerably homogeneous mass of new-formed tissue. But when the granulating mass attains the general level of a free surface, such as that of the skin, its further growth under ordinary circumstances becomes arrested, epidermis begins to shoot from the normal epidermis at the margins over the edges of the granulating area, which at the same time contracts, and soon, if it be of small size, gets completely covered. It is even now a disputed point whether a granulating surface has any power of itself to generate epidermic cells. It is certain, however, that the chief development of new epidermis begins from old epidermis, that very large breaches of surface never become thus covered unless aided by artificial means, and that the grafting here and there, upon such a surface, of small fragments of epidermis results in the formation of a number of epidermic islets, from which new epidermis spreads radially. In the healing of a clean cut, of which the edges are placed in close apposition, the process is nearly the same as that of the organisation of false membranes. The divided vessels pour out blood and serum, containing fibrinogen; this coagulating entangles corpuscular elements, and cements the divided surfaces; and presently the white corpuscles thus entangled, and others which migrate among them, emit processes and form a network, mapping out the fibrinous cement into comparatively small islets. The further steps of the process present no peculiarity.

The ultimate product of inflammatory organisation is generally what is commonly termed 'cicatricial tissue': a form of connective tissue presenting much hardness and compactness, comparatively little vascularity, small and widely scattered plasmatic cells, and relatively abundant and dense interstitial substance; which becomes bony when developed in connection with bone, and contains fat when it replaces normal fatty tissue; but which, while it is capable of reproducing, with more or less imperfection, the various tissues comprised in the connective-tissue group, rarely results in the production or development of higher tissues, such as muscle, and probably never in the formation of organs. Hair and glands, for example, never appear in entirely new-formed skin.

In some cases the results of inflammatory proliferation are somewhat different. The process gets chronic, cell-generation goes on comparatively slowly, and the newly formed tissue, instead of contracting and hardening, becomes swollen and perhaps softer than natural, and forms, in fact, an increasing projection or lump, in which the cell-elements remain predominant, but tend to fatty and other forms of degeneration. Such results are seen in keloid and in some forms of arterial atheroma.

*g. Spread.*—The tendency which inflammations have to spread is at least as remarkable as that presented by other proliferating affections. If a patient has local eczema, produced by the application of some irritant, presently other patches of eczema appear in the neighbourhood; if he has a boil, it commences in a point, and increases by involving more and more of the surrounding tissues, and soon other boils arise in its vicinity; in erysipelas and pneumonia, and in inflammations of serous and mucous

membranes, the same rule of local spread, or spread by simple continuity, is even more obvious. But inflammations also tend, in many cases, to spread through the agency of the lymphatics and veins, and thus to involve remote parts, and other tissues besides those first affected. Thus, suppuration, occurring in a toe or finger, is apt soon to be followed by inflammation in the course of the lymphatic vessels, and of the lymphatic glands in the groin or axilla; and indeed generally there is a tendency, if the local inflammation be sufficiently intense, for the nearest lymphatic glands to get implicated. And thus again, in certain cases, inflammatory processes become generalised by means of the circulating blood, so that tracts of inflammation, secondary to some primary tract, appear, either simultaneously or in quick succession, in various parts of the body. Ordinary pyæmia furnishes a typical example of this connection; and it is not impossible that the frequent association of inflammation in different organs, and even the invasion of successive joints in acute rheumatism, may admit of similar explanation.

*h. Constitutional effects.*—We must not forget to consider, however briefly, the influences which inflammatory processes going on in one part of the system exert on the system generally. Patients who are suffering from acute inflammations are soon affected with febrile symptoms. To what are they traceable? In some degree, no doubt, to the direct influence which abundant local proliferation of tissue exerts generally upon nutrition. It will be recollected, however, on the other hand, that the copious and active proliferation attending the formation of an extensive surface of granulations, or the development of the fœtus, produces no such constitutional disturbance. But, indeed, the inordinate consumption of nutrient matter is certainly not the main cause of the constitutional symptoms of inflammation. It has been proved by direct observation that a part generates much more heat when inflamed than when in its normal state; and that the blood in the veins coming from an inflamed area is distinctly hotter than the blood brought thither by the arteries. It is certain, therefore, that a part of the febrile temperature of the system must be due to the dispersion of this excessive locally produced heat. Again, as we have already pointed out, wherever inflammatory proliferation is active, there also the processes of effusion from the blood-vessels, of molecular disintegration, and of lymphatic absorption, are specially active; and thus large quantities of modified nutrient fluid, and of products of decay, are being constantly removed from the seat of disease and poured through the thoracic duct into the systemic veins. It seems highly probable that here is the source of the comparatively large presence of fibrinogen which is so characteristic a feature of the blood of inflammation, and that here also is the main source of the excess of urea and other products of retrograde metamorphosis, which are presently discharged by the various emunctories. There can be no doubt that the general symptoms of inflammatory fever are largely due to the heightened temperature, and to the alteration and deterioration of the blood, which have been thus produced—conditions which, according

to their amount, must necessarily influence in a greater or less degree the nutrition and the functions of all parts of the system. It is certain too: that the nervous system, mainly by its vaso-motor branches, plays an important part in the production of febrile disturbance, though what that part is is not easy to identify; and that the symptoms of inflammatory fever are largely modified, chiefly in the way of complication, by the interpolation of other symptoms, due to the modification, impairment, or destruction of the normal functions of the organ which happens to be affected.

*i. Varieties.*—In the foregoing pages we have discussed the phenomena of inflammation in the abstract; our account of inflammation would scarcely be complete, however, if we failed to point out some of its varieties: varieties depending partly on the intensity of the process, partly on the organ implicated, and partly on the nature and mode of operation of the cause; and revealing themselves as such, either by their extent and arrangement, or by their special tendencies, or by their duration. It need scarcely, perhaps, be pointed out, that we trench here upon the domain of specific diseases, or diseases in which the inflammation is a mere secondary phenomenon, excited and kept up by the operation of some specific irritant, which has been received into the system and then distributed through it. But, indeed, as knowledge advances, we see more and more clearly that in every case of inflammation which comes before us, the inflammation has been excited by some cause which imparts to it certain distinctive features—that it is specific—and we recognise the fact, half-unconsciously perhaps, by distinguishing most varieties of inflammation by specific names.

*i. Varieties as to extent and arrangement.*—In many cases inflammation pervades, with tolerable uniformity, the whole of an organ or tissue—such is the case in pneumonia, peritonitis, erysipelas, and pityriasis rubra; in many cases, it is irregularly distributed in patches or spots, as in the rashes of typhus and enteric fevers, in urticaria, shingles, and lobular pneumonia; in other cases it assumes certain definite patterns—disks in lepra, rings in erythema circinatum and ringworm, crescents in measles, and sinuous bands in some cases of secondary syphilis.

*ii. Varieties as to result and intensity.*—It is certainly a striking fact that some forms of inflammation, no matter how severe they may seem, or threaten, to be, never pass beyond the earlier stages of the process; while others, which commence probably with the mildest indications, invariably go on to suppuration or gangrene. In such diseases as measles, pityriasis, and lepra, the local phenomena of inflammation are always exceedingly slight, and consist in little more than hyperæmia in patches, followed by modification, and then detachment, of the overlying epidermis. In urticaria, the process, if more intense for the time, is far shorter in its duration: for here we get pretty intense congestion, with rapid effusion of serum into the congested tissues, which subsides in a few hours or even in a few minutes, and is rarely followed even by desquamation. In eczema, herpes, and pemphigus, the local congestion is always attended with

abundant effusion of serum beneath the epidermis. Now, in all the above cases, notwithstanding the marked differences of detail which they exhibit, the changes are rung only on mere congestion and effusion, together with (as is of course always the case) a certain amount of nutritive change, if not of actual proliferation. In other cases suppuration seems to occur almost invariably; it is so with small-pox and cow-pox, impetigo and ecthyma; and in inflammation affecting the periosteum, and the womb immediately after parturition, this suppurative disposition is extremely well marked. In other cases, again, the tendency of the inflammation to end in the death of tissues, that is in ulceration or gangrene, is a characteristic feature; as examples we may adduce erysipelas, carbuncle, and hospital gangrene.

iii. *Varieties as to duration.*—Inflammations are acute or chronic in their progress. Acute inflammations are sometimes, as in factitious urticaria, remarkably evanescent. Chronic inflammations are chronic in different fashions: in some instances the inflammatory process, as in the case of a patch of psoriasis on one of the knees, or of a sinus constantly discharging pus, is continuous and of long duration; in a larger number of cases chronicity is due to a succession of acute attacks, each one of which may have but little intensity. It is thus that urticaria assumes the chronic form of urticaria evanida, and that erysipelas and eczema become perpetuated; we may add to the list rheumatism and gout. It seems probable also that cirrhosis of the liver, referrible to alcohol, is rendered chronic by the repeated irritation induced by the repeated application of the alcoholic poison. It is in these latter forms of chronic inflammation, more especially, that the proliferation of tissue, which attends all inflammations, becomes constant, and leads to a substantial addition to the normal bulk of a part; that bones acquire increased thickness and density; and that the interstitial tissue of the liver, kidneys, lungs, and nervous centres gets augmented in quantity, and by its augmentation leads to the gradual destruction of the essential glandular elements.

k. *Relation of inflammation to septic organisms.*<sup>1</sup>—Of the important relations subsisting between micro-organisms and some kinds of infective inflammations there can be no doubt. There are some persons, indeed, who regard all inflammations as the product of septic organisms; and Hueter, a distinguished advocate of this hypothesis, says expressly, ‘Septic organisms exist everywhere, ready, wherever access is offered to them, to enter the body and fulfil their morbid function; consequently inflammation may be defined, with reference to the universality of its cause, as an epidemic and contagious disease which prevails universally over the whole world, with the exception of mountainous regions, near and above the line of perpetual snow.’ There is more reason to believe, with Sander-son and others, that while inflammation may be excited by any local irritant, its spread or diffusion, and its communication from one person to another, are determined only by the agency of such organisms; or, in

<sup>1</sup> See Dr. Burdon Sanderson’s *Lumleian Lectures on Inflammation*.

other words, that inflammation caused by simple irritation remains strictly limited to the parts irritated, and incommunicable, that inflammation caused by septic organisms is alone infective and infectious, and that whenever simple inflammation acquires such properties its spread is due to the superadded agency of the bodies referred to. ✓

*Note in reference to Recent Views as to the Nature and Processes of Inflammation*

It was taught by Virchow, and accepted implicitly for many years, that the essence of inflammation is irritative growth and proliferation of the stationary protoplasmic elements of the tissues involved in inflammation, resulting in the formation of abundant embryonic corpuscles or pus-cells; and that the associated phenomena of the accumulation of blood plasma in the tissues, the dilatation of the blood-vessels with retardation or stagnation of their contents, and others which need not be enumerated, are secondary to the processes occurring externally to the vessels, and to a large extent determined by nervous influence. The discovery of Cohnheim, that in inflammation (even the inflammation of extra-vascular tissues) leucocytes escape in large numbers through the walls of the distended capillary veins and other small vessels, find their way abundantly into the interstices of the connective tissue, and accumulate in the very parts in which previous observers believed they had witnessed the development of similar cells from the germination of connective-tissue and other corpuscles, naturally tended to throw some doubt on the trustworthiness of these observations. It then came to be generally held (in accordance with the account already given, and provisionally adopted) that the source of inflammatory corpuscles (pus-cells, leucocytes, and the like) in inflamed area is twofold, namely, the multiplication of stationary protoplasm, and the immigration of the white corpuscles of the blood; and the phenomena observed when the centre of the cornea is irritated were (as we have shown) appealed to in proof of this double origin. Later investigations, however, render it more and more probable that all inflammatory corpuscles, all pus-cells which appear or accumulate in inflammation, are simply immigrant white blood corpuscles; and that no such local proliferation as was formerly described ever takes place, or at any rate ever takes place as the direct consequence of the irritation causing inflammation. The phenomena, indeed, observed in corneal inflammation are now appealed to as confirming this view. It appears, in fact, that the localised area of opacity taking place around a central point of irritation, and which is due to the accumulation of inflammatory corpuscles, does not take place unless the epithelial covering of the cornea be damaged or removed, and that it is due immediately, and alone, to the entrance through the breach of leucocytes, or bodies resembling them, which abound in the sac of the conjunctiva.

If this exclusive origin of inflammatory corpuscles and pus in an inflamed area be admitted, the hitherto accepted views with regard to the

theory and processes of inflammation need important modifications in other respects also. It is clear that if the local effects of pathological irritation be not overgrowth, proliferation, and exaltation of function of the irritated living elements, either these elements maintain their normal state of health under the adverse conditions in which they are placed and remain unchanged, or their vitality becomes impaired in a greater or less degree or destroyed. Of the inadmissibility of the former alternative there is abundant proof. We know, on the other hand, that at any rate in large proportion the living tissues are actually damaged or destroyed in regions that are inflamed; and there is little or nothing therefore (apart from the supposed fact of local proliferation) to render it improbable that the impairment or necrosis of living tissue is the necessary and universal immediate consequence of irritation inducing inflammation, and the fundamental fact of inflammation.

According to the above hypothesis: all inflammation is a local phenomenon; its origin is damage done to the part which subsequently inflames—damage which, if slight, may allow of recovery, if severe, may necessitate death; the immediate effect of the damage is that the protoplasmic masses distributed throughout the part become weakened physically and functionally, and that the imbedded vessels therefore become weakened, and dilate under the normal pressure of the blood within them; the vessels thus passively enlarged permit of the accumulation of blood in their interior, and consequently of retardation of the blood-stream, with separation of the red and white corpuscles and tendency of the latter to take a peripheral position; this stagnation of blood in the vessels involves the transudation (through their walls into the tissues around) of the blood-serum, with its albumen, and the formation of fibrine, and further (if the vessels become completely occluded) increased impairment or destruction of tissue; the so-called ‘vital processes of inflammation’ which determine the removal or repair of the tissues devitalised by inflammation, and which comprise the migration of leucocytes and their accumulation in the diseased area, and the growth or development taking place in the healthy protoplasmic masses immediately surrounding that area, form no part of the inflammatory process, and are simply reparative in their tendency.

It follows, from what precedes, that redness, heat, swelling, and (if nerves be involved) pain are the natural consequences of simple impaired vitality of tissues, and that, even on the new hypothesis, the clinical signs of inflammation remain the practical tests of inflammation.

#### 4. Tumours

*General account.*—It would be foreign to the purpose of this work, and to a great extent out of place, to enter into anything like a minute account of the various forms of tumours described by pathologists. We purpose, however, to pass them generally in brief review—describing at greater length such as have a special relation to the practice of medicine, and a special interest therefore for the physician. Tumours, in the

proper sense of the term—that is, morbid proliferating growths, or neoplasms—have a very close affinity with simple hypertrophy or hyperplasia on the one hand, and with mere inflammatory overgrowth on the other. Structurally considered, they are in truth, in many cases, a simple hyperplasia or overgrowth of normal tissue, differing, however, from true hyperplasia in the facts : first, that they are overgrowths occurring in a limited district ; and second, that their growth has no relation to the general growth of the tissue out of which they spring, or to the general nutrition of the body. In many cases, again, tumours and simple inflammatory overgrowths seem structurally identical.

Tumours have been variously classified. They have been divided into the two large groups of *cystic* and *solid* tumours. But cysts, although a very characteristic feature of some new formations, are for the most part merely incidental to them, and their presence or absence can in no sense furnish the basis of a scientific classification. Again, they have been distinguished into those which are *innocent* and those which are *malignant*. The question of the malignancy or non-malignancy of a tumour is always, in a practical point of view, of supreme interest ; and it may be allowed that, in a large number of cases, malignancy is linked to special structural characters, and may be predicted from them. But, on the other hand, it is now generally admitted that malignancy varies in degree, and that few if any proliferating growths are wholly free from liability to assume malignant properties. Virchow, accepting the law which J. Müller enunciated (namely, that ‘the tissue which constitutes a tumour has its type in one of the tissues of the organism, either in its embryonic condition or at the period of its complete development’), classifies tumours according to their structural relations with the normal tissues of the body. Such a classification is at once scientific and intelligible ; and although many difficulties, and much room for difference of opinion, present themselves when it is attempted to carry it out in detail, there can be little doubt that it is sound in principle. But admitting that all tumours have their types in the normal tissues, it does not always happen that a tumour has its type in the precise tissue in which it originates. When a tumour arises in a tissue from which it takes its pattern, it is regarded by Virchow as ‘homologous’ ; when, on the other hand, it is developed in a tissue which it does not thus resemble, he calls it ‘heterologous.’ The latter term has often been used of malignant tumours, in the belief that they are something altogether different and distinct from the normal elements of the body—something, in fact, of the nature of parasites ; and it is well to know that, even in the more accurate and limited sense in which Virchow employs it, it still carries with it the sense of malignancy. Most malignant tumours are heterologous.

Virchow divides tumours into four groups, as follows :—1, tumours formed at the expense of the elements of the blood, or tumours by extravasation and exudation ; 2, tumours referrible to the retention of products of secretion and the consequent dilatation of ducts or cavities ; 3, tumours originating in proliferation, which he subdivides into *histioid*, or such as

are formed out of a single tissue, *organoid*, or such as are characterised by greater complexity and an approach to the structure of organs, and *teratoid*, or those comprising a combination of organs; and 4, or lastly, complex tumours, in which features characteristic of two or more of the foregoing groups are combined. The first two of Virchow's groups embrace a series of pathological results which can only be regarded conventionally as tumours; all true tumours are included in his third and fourth groups.

We may here advert to the theory of the origin of morbid growths, first clearly formulated by Cohnheim, and since largely adopted by pathologists in reference at any rate to certain forms of tumours; namely, that they arise in unused fragments of rudimentary tissues, which from the time of foetal life have lain quiescent in the organism until accidental circumstances have aroused their latent vitality. Such fragments are probably the sources of many heterologous growths, and of all teratoid and complex tumours. Mr. Bland Sutton has drawn especial attention to the fact that teratoid tumours arise chiefly if not exclusively in connection with obsolete or disused canals or ducts, which in the beginning are in close relation with all three blastodermic layers, and hence endowed with large potentialities for complex development.

We shall not discuss the details of Virchow's classification, nor shall we reproduce here the convenient modification of it which Cornil and Ranvier have published; yet, in the brief account of tumours which we are about to give, we shall be guided in a very great degree by the views of these authors. Indeed the modifications, mainly of arrangement and proportion, which we shall introduce, will have reference almost entirely to convenience of description and to clinical considerations. We shall arrange tumours (omitting, as will be observed, all further reference to the teratoid and complex forms) in the following groups:—

*a*, tumours which have their types in the various forms of connective tissue: this includes the fibrous tumour or *fibroma*, the fatty tumour or *lipoma*, the mucous-tissue tumour or *myxoma*, and one or two less important varieties:

*b*, tumours composed of cartilaginous tissue, or *chondromata*;

*c*, osseous tumours, or *osteomata*;

*d*, tumours formed of nervous tissue, or *neuromata*;

*e*, tumours consisting of muscular tissue, or *myomata*;

*f*, vascular tumours or *angiomata*;

*g*, tumours consisting of lymphatic tissue, or *lymphomata*;

*h*, *sarcomata*, or tumours which resemble embryonic tissue;

*i*, tumours presenting an alveolated structure—the alveoli being formed of connective tissue, and occupied or lined by closely packed epithelium-like cells. All these are embraced in the general term *carcinoma* or *cancer*.

*j*, *granulomata*, or tumours resembling granulation-tissue. These are for the most part, if not always, infective, and (there is reason to believe) due to organised contagia.

## a.—Connective-tissue Tumours

i. *Fibrous tumour, or fibroma*.—Tumours of this kind consist essentially of connective tissue—that is, of a network of plasmatic cells, separated from one another by bundles of white fibrous tissue and different proportions of elastic fibres; the last, indeed, are often absent. They are rosy, greyish, yellowish, or white in tint; are sometimes dense and close-grained like fibro-cartilage, sometimes soft, loose in texture, and succulent; are provided for the most part with scanty and small blood-vessels, and are occasionally non-vascular; and often, when involving a mucous or a serous surface, involve also the glandular and papillary structures, which then undergo hypertrophy. Fibrous tumours often originate in the subcutaneous connective tissue, and also in the substance of the skin—producing warts or papillomata, ‘molluscous’ tumours, and it may be pedunculated masses of enormous bulk. Again, they are frequently developed in connection with mucous surfaces, forming mucous polypi. The opaque cartilage-like patches seen on the surface of the spleen, heart, and other viscera, are fibromata; but their plasmatic cells are scanty, indistinct, and much flattened, the fibrillated intermediate substance is densely stratified, and they are without vessels. The thickening and induration of the skin and subcutaneous connective tissue, in elephantiasis Arabum, are chiefly due to the growth of connective tissue, and constitute a diffused form of fibroma. It is very difficult to separate, by a defined line, the results of chronic inflammation from fibromatous tumours, especially from the diffused forms of fibroma. Indeed, papillary growths and polypi are frequently a simple sequela of ordinary inflammatory processes; and further, there is little if any real difference between the forms of fibroma involving the pyloric extremity of the stomach, or the substance of the mamma, which we generally regard as of the nature of tumours, and the fibrous growth invading the liver in cirrhosis, which is commonly considered to be simply inflammatory. Fibrous tumours are apt to undergo various forms of degeneration, especially the fatty, mucous, and calcareous. They are almost invariably free from malignant tendency.

ii. *Fatty tumour, or lipoma*.—Fat is a mere modification of connective tissue, in which the plasmatic cells have become distended with oil, so that their protoplasm and nuclei can only be recognised with difficulty, and they themselves are transformed into globular, or (from mutual pressure) polyhedral, bodies. Fatty tumours consist, for the most part, simply of newly developed fat-tissue, and present little if any structural differences from normal fat. They vary in size, and generally are lobu-

FIG. 6.—FIBROMA FROM SURFACE OF SPLEEN.  $\times 250$ .

lated, and capable of pretty easy enucleation from the tissues in which they are imbedded; but sometimes their limits are ill-defined, and they pass gradually into the normal textures. Lipomata often originate in the subcutaneous connective tissue, and occasionally in the submucous and subserous tissues; also in the neighbourhood of glandular organs; and indeed generally wherever fat exists naturally. Not unfrequently they form polypi or pedunculated tumours. There are several well-defined varieties of fatty tumours: one, which may be called *fibrous lipoma*, is characterised by the presence of abundant fibrous tissue; another (the *myxomatous lipoma*) presents the combined characters of myxoma and lipoma; a third is the *cystic lipoma*; and the last which we may enumerate is the *erectile* or *cavernous lipoma*. Further, fatty, like fibrous tumours (to which they are closely related), are liable to undergo calcareous and other forms of degeneration, and are probably always innocent.

iii. *Mucous tumour, or myxoma*.—Mucous tissue, which is common in the foetus, exists permanently only in the vitreous humour. The tissue

FIG. 7.—MYXOMA.  
a. (H. Arnott). b. (Cornil and Ranvier).

of the umbilical cord furnishes a typical example of it. It consists of plasmatic cells, which are generally stellate like those of connective tissue or bone, and of an intercellular substance, which, instead of being solid, as in these latter cases, is transparent and fluid and contains mucine, or the characteristic constituent of mucus. Myxomata are lobulated tumours, gelatinous in consistence, translucent, and yielding a transparent, glairy, never milky, fluid. Under the microscope they are seen to consist of scattered cells, round, oval, or stellate, and an abundant network of capillary vessels, separated from one another by the structureless fluid, or

semi-fluid, mucus, which gives them their specific character. They vary in colour and consistence according to the relative proportions of cells and mucus which they contain, being more opaque and denser as the cellular element predominates. They originate in most places in which normal fat occurs, and indeed there seems to be some definite relation between them and fat. But they occur elsewhere. Their most common seats are the subcutaneous and submucous tissues, and the connective web between muscles; but they are not unfrequently met with in the brain and in the course of nerves, in glandular organs such as the breast and kidney, and beneath the periosteum. In connection with the skin and mucous membranes, they often form papillary or polypoid outgrowths. Placental hydatids are a good example of this latter variety. Sometimes myxomatous tumours contain cavities (*cystic myxoma*), or their cells get distended with fat (*lipomatous myxoma*), or their intercellular mucus tends to condense and become cartilaginous (*enchondromatous myxoma*), or their vessels are extraordinarily abundant and large (*vascular or erectile myxoma*). Myxomata, when not occurring in situations where fat is normally present, must be regarded as heterologous; and they then occasionally present malignant characters. Generally, however, they are innocent, and do not even return after removal.

iv. *Glue-like tumour, or glioma*.—This is a tumour which, according to Virchow, consists of connective tissue resembling that of the nervous centres; and in fact it originates almost exclusively in these centres, in the course of nerves, and in the retina. The neuroglia consists of very small and delicate cells, imbedded in a finely granular or amorphous substance. These have a tendency to be stellate, and, in carefully prepared sections, appear to unite with one another by their rays, so as to map out the intervening substance into small polygonal areas. Gliomatous tumours present the same structure, and are generally white and medulla-like in aspect, and exceedingly soft. They vary no doubt considerably, in respect of the relative proportions of their cellular and inter-cellular elements, and in their tint, consistence, and vascularity; and they run, on the one hand into myxoma, on the other into the small round-celled variety of sarcoma, with one or other of which it is difficult to avoid confounding them. They are apt to undergo mucous, caseous, or fatty degeneration, and to become cystic. The situations which they affect, and the tendency they have to attain a large size, render them dangerous; but they are rarely malignant.

#### *b.—Cartilaginous Tumours, or Chondromata*

Chondromata consist of cartilaginous tissue: that is, of cells surrounded by lamellated thickenings, and separated from one another by chondrine-yielding intercellular substance; which is generally hyaline, as in ordinary articular cartilage, but may be reticulated as in yellow cartilage, or fibrous as in fibro-cartilage. Cartilaginous tumours have for the most part a slightly translucent or pearly aspect, and a whitish or yellowish hue.

They vary greatly in consistence, being sometimes dense, hard, and crisp, sometimes forming a diffuent pulp. They are generally distinctly lobulated, the lobules being separated one from another by connective tissue, which conveys their nutrient vessels, for the cartilaginous tissue itself is entirely extra-vascular. The tumours are for the most part perfectly well-defined; but they are sometimes irregularly diffused through the tissues or organs in which they originate. Under the microscope they present many varieties of character. Their cells vary in size and number, but are always encapsuled; they are generally round or oval, but may be branched or stellate like those of the cornea; further, they not unfrequently undergo fatty or calcareous degeneration. The intercellular substance, which, as previously stated, may be hyaline in character, or consist in part of either white fibrous tissue or elastic fibres, sometimes softens into a mucous fluid in which the cartilage cells are simply suspended. Chondromata in this latter condition have a resemblance to the

FIG. 8.—CHONDROMA.

*a.* Section of growth.  $\times 250$ . *b.* Calcifying cells.  $\times 250$ .

intervertebral cartilages; and it is by such softening in patches that they occasionally become cystic. Virchow divides chondromata into *ecchondroses* and *enchondromata*. The former are merely outgrowths from normal cartilages, and are therefore homologous; they never attain important dimensions, are invariably innocent, and very apt to be converted into true bone. The most interesting examples of ecchondrosis are the cartilaginous outgrowths which take place in joints affected with chronic rheumatoid arthritis. Enchondromata are heterologous; they occur most frequently in bones, especially in the long bones; but they are also met with in the subcutaneous connective tissue and aponeuroses, in the lungs, parotids, testicles, ovaries, and mammary glands. Enchondromata generally no doubt are innocent; but they certainly are sometimes distinctly malignant, extending along lymphatic vessels involving lymphatic glands, and ultimately invading remote organs.

*c.—Osseous Tumours, or Osteomata*

Osteomata are generally divided into three species—namely, *icory osteomata*, *compact osteomata*, and *spongy osteomata*. The first species is met with on the inner surface of the skull, and at the joint ends of bones and elsewhere; it is characterised by remarkable compactness of tissue, and under the microscope presents bone corpuscles and canaliculi (which latter run radially to the surface), and a total absence, or great deficiency, of Haversian canals, and hence of vessels. Compact osteomata present the ordinary characters of compact bone. Spongy osteomata, as their name implies, resemble more or less closely the spongy or cancellous tissue. Osteomata springing from the surfaces of bones are known as *exostoses*; those originating in the substance of bones may be named *enostoses*. Both varieties are clearly homologous. But osseous tumours are sometimes heterologous. Thus, they appear in the connective tissue, in the membranes of the brain and cord, in the brain itself, in the choroid and vitreous humour of the eye, in the lungs and in the skin. True osteomata, even when heterologous, are probably never malignant. Nevertheless tumours, which have undergone more or less perfect conversion into true bone, are sometimes malignant in a very high degree. Such tumours, however, are made up in great measure of cartilaginous or embryonic tissue, and should probably be regarded as chondromata or sarcomata which have undergone calcareous or osseous transformation.

The teeth occasionally present outgrowths of their own tissue, which have been named *odontomata*.

*d.—Nervous Tumours, or Neuromata*

The term 'neuroma' is often applied loosely to all growths occurring in the course of nerves; and thus myxomatous, fibrous, and various other equally distinct tumours have, to a large extent, been regarded as varieties of neuroma. Neuroma, in the strict sense of the word, means a tumour formed of nervous tissue: either vesicular, like that of the ganglia or central nervous organs, or fasciculated like that of the nerves or medullary substance of the brain. The former variety is exceedingly rare, but has been described as occurring in the brain and spinal cord. The latter variety is more common, but nevertheless of unfrequent occurrence, and is met with only in the course of nerves. True fasciculated neuromata generally are small white hard tumours, occurring singly or in numbers along a nerve-trunk, or more commonly at the extremities of nerves, which have been divided in the amputation of a limb. They are invested with, and permeated by, very dense fibrous tissue, the presence of which makes them difficult of examination; but their essential character is that they contain a large number of newly developed nerve-fibres, which form an abundant and intricate network. These generally have the double contour; but neuromata containing only pale fibres have been described.

*e.—Muscular Tumours, or Myomata*

Striped muscular fibres have been discovered only in congenital tumours. Unstriped muscular fibres, on the other hand, are of common occurrence in morbid growths. Myomata are most frequently met with in the uterus, and it is in connection with the uterus that their characters may best be studied. The so-called ‘fibrous tumours’ of this organ are, almost without exception, muscular tumours. These vary greatly in size, have a reddish or greyish fleshy aspect, are generally exceedingly dense, and present a lobulated character with curvilinear bands of fibres interlacing with great complexity. They always originate within the walls of the uterus, and hence, in the early stage, are surrounded by the uterine muscular tissue; but if seated near either the mucous or the serous surface, they are apt ere long to protrude through the fibres which embrace them on that side, and presently to become pedunculated. Microscopically, they are found to be identical in structure with the uterine muscular walls. Further, like them, they are capable of hardening in contraction,

FIG. 9.—MYOMA FROM UTERUS AT FULL TERM.  $\times 250$ .

and again of undergoing relaxation. Moreover, they increase during pregnancy as the uterus itself increases—their muscular fibres undergoing similar and equal hypertrophy; and when, after parturition, the uterine walls undergo involution, they also suffer in the same sense. Uterine

muscular tumours frequently degenerate:—the muscular fibre-cells get fatty, or their tissue undergoes mucous transformation—considerable patches becoming softened and infiltrated with mucous fluid, and not unfrequently converted into cysts; but the most frequent and important change is due to the deposition of calcareous matter, partly in the connective tissue of the tumour, partly in its muscular fibres, by which means nearly its whole substance may at length be converted into a hard calcareous mass. This latter form of degeneration generally commences in the interior; occasionally, however, it starts from the periphery, and it may remain limited to the periphery. Myomata rarely, if ever, originate except in tissues which themselves contain muscular fibres. After the uterus, they are most frequently met with in the prostate and alimentary canal. They have also been found in the scrotum, labia majora, and ovaries. They are always innocent.

*f.—Vascular Tumours, or Angiomata*

Several of the tumours which have already been described, and several of those which we shall presently discuss, are liable to be exceedingly vascular (partly from excessive formation, partly from general and irregular dilatation, of blood-vessels), and thus to assume an erectile or cavernous character. And, indeed, although we have adopted the name 'angioma' for a group of tumours, there are few, if any, in which vascular hypertrophy or hyperplasia constitutes the sole, or even the essential, characteristic. Angiomata may be conveniently divided into two species, in the one of which the newly developed vessels are properly formed arteries, veins, and capillaries, and in the other of which the blood traverses a series of lacunar spaces, like those of erectile organs. The former may be called 'simple angiomata,' the latter 'cavernous angiomata.' *Simple angiomata* form violet or red, more or less elevated, patches, the general seat of which is the skin or subcutaneous connective tissue. Their vessels are abundant, tortuous, and dilated, and often present irregularities of calibre, and even pouch-like protrusions. Amongst these must be reckoned the small racemose knots, which often make their appearance on the face and elsewhere (sometimes in considerable numbers), and in which the chief morbid phenomenon is dilatation of small arteries and veins. *Cavernous angiomata* are also known by the name of *erectile tumours*. They occur in the skin and subcutaneous connective tissue, in the neighbourhood of the external mucous orifices, and in some of the internal organs, more especially the liver and spleen. They have a spongy character, which is due to the comparatively large size of their vascular lacunæ, and the comparatively small amount of their solid tissue. The lacunæ are irregular in size and shape, communicate freely with one another, and are lined with a layer of flat epithelial scales. The solid or trabecular element consists mainly of connective tissue, in which the ramifications of small vessels and unstriated muscle are sometimes contained. Angiomata are often congenital, and are entirely free from malignancy.

FIG. 10.—ANGIOMA.  $\times 250$ .

*g.—Lymphatic Tumours, or Lymphomata*

The important relation which subsists between the lymphatic vessels and glands, on the one hand, and morbid proliferation of tissue, on the other, has already been explained. We have shown, that when inflammatory processes are taking place in any part, the nearest lymphatic

glands tend soon to get inflamed; that, if the local inflammation has specific characters, the resulting affection of the lymphatic glands shares in these characters; and that, in all cases of malignant tumour, it is the neighbouring lymphatic glands which, next in order of sequence, become the seat of malignant growth. So that, in fact, in the morbid proliferations of these bodies, we have an epitome of the morbid proliferations of the whole organism; and to describe their tumours would be equivalent to writing a complete treatise on tumours. What is meant, however, by the term lymphatic tumour, or lymphoma, is an hypertrophy or hyperplasia of lymphatic structure, and the new formation of similar structure in parts where normally lymphatic organs have no existence. Under the name 'lymphoma' may be included two perfectly different morbid conditions:—the one, an abnormal development of lymphatic vessels, or *lymphangioma*; the other, an abnormal development of lymphatic gland-structure, or *lymphadenoma*.

i. It is doubtful if *lymphangioma*, as an independent morbid growth, has any existence. There are many cases, however, in which enlargement, and possibly over-development, of lymphatic vessels forms an important ingredient in the morbid conditions which are present. Virchow has shown that, in elephantiasis Arabum, hyperplasia of the connective tissue is largely associated with a dilated and hypertrophic state of the lymphatic vessels, and especially of the lymphatic spaces in which they originate. This change seems, however, to be secondary to obstruction of the lymph-paths through the inflamed lymphatic glands, to which the dilated tubes converge. In congenital hypertrophy of the tongue and lips, the same authority has pointed out the presence of a similar condition of the lingual lymphatic vessels. Further, cases are occasionally observed, in which the penis and scrotum, or corresponding parts in the female, or the lower part of the abdomen, or the thigh or leg, are thickened and brawny; and in which groups of depressed vesicles appear here and there, and, rupturing from time to time, yield large quantities of pure lymph. Here, the hypertrophy of the skin and subjacent parts, and the formation of vesicles, are doubtless all due to dilatation of the lymphatics, and their distension with lymph—phenomena which probably are themselves secondary to some proximal obstructive disease.

ii. *Lymphadenoma*.—There are at least three morbid conditions of the lymphatic glands which, if we have regard only to anatomical characters, are extremely difficult and often impossible to distinguish from one another. These are, simple inflammatory hyperplasia, the so-called 'scrofulous' form of enlargement, and that morbid condition now generally known as lymphadenoma, or lympho-sarcoma, and to which also the names 'Hodgkin's disease' and 'adenia' have been given.

a. *Simple inflammation* of lymphatic glands may be induced by causes acting directly upon them, but is much more commonly the result of irritation propagated to them along the lymphatic vessels. They enlarge and get painful, assume a homogeneous aspect and a yellowish or faint rosy tinge, and under the microscope are found to differ but little from

healthy glands—their enlargement being due to simple hyperplasia of their cell-elements, or leucocytes, and to hypertrophy of their reticular connective tissue. Lymphatic glands thus affected may suppurate, or undergo other of the changes which are apt to follow on inflammation; but their general tendency is to resolution.

β. The term *scrofulous* is commonly applied to the slow and painless enlargement of groups of lymphatic glands, which occurs for the most part in children, and almost invariably ends in the destruction of the glands by an imperfect kind of supuration. Scrofulous glands are generally met with in either the neck, the thorax, or the abdomen, and are commonly limited to one of these regions. Indeed, in the neck, where their progress can best be followed, we often see that the enlargement commences in one gland; that the glands in the vicinity are successively affected, and often at long intervals; and that, after a while, the morbid process ceases with the destruction of all the implicated glands—those on the opposite side of the neck possibly remaining all the time perfectly healthy. In the earlier stages of this affection, the glands differ little, either to the naked eye or under the microscope, from such as are simply hyperplastic from inflammation; but they tend soon to become opaque, yellow, and friable—to undergo caseous degeneration. This change commences in the central parts, and gradually involves the whole mass, which presently breaks down into a semi-fluid detritus and thus forms the imperfect pus previously adverted to. Occasionally the caseous lump dries up, earthy salts are deposited in it, and it becomes an inert earthy concretion. There is a good deal of vagueness in the sense in which the term ‘scrofulous’ is generally employed. The truly scrofulous glands are tubercular.

γ. The affection now generally known as *lymphadenoma* differs but little anatomically from the morbid conditions which have just been described. It is characterised, like them, by a simple overgrowth of lymphatic tissue—that is, by a development of cells, which essentially resemble ordinary leucocytes, but are sometimes large and multinucleated, in the meshes of a trabecular tissue like that of normal lymphatic glands. The cells here, as in healthy glands, are so abundant that, in an unprepared section, they conceal all other elements; but if they be removed by pencilling or washing, the fibrous matrix and vessels come into distinct view. The lymphatic glands in this affection, and other parts which become implicated, rapidly increase in bulk, acquire for the most part an opaque milky aspect, soften, and yield, like carcinoma, a milky juice. They are liable also to fibroid and to fatty and caseous degeneration, and to be the seat of hemorrhage.

Lymphadenoma is generally distinguished, from both simple inflammation and scrofulous proliferation, by the following important facts: first, that the morbid process tends pretty rapidly to involve the lymphatic glands distributed throughout the organism; and second, that there is a disposition to heterologous development of identical morbid gland-tissue in situations in which normal gland-tissue has no existence.

In other words, lymphadenoma must be looked upon as a variety of malignant disease, in which the secondary as well as the primary growths assume the microscopical characters of lymphatic tissue. It should be remarked, however: in the first place, that by lymphatic or adenoid tissue is not meant the whole complicated organism of lymphatic glands, but merely that comparatively simple arrangement of reticulated fibres and leucocytes which is found in the solitary intestinal glands, and in the Malpighian bodies of the spleen; and, secondly, that the recent investigations of several German physiologists, and of Burdon Sanderson in this country, have shown that lymphatic tissue is very abundantly distributed throughout the body (amongst other places in the subserous tissue, in the submucous layer of the intestine, and along the bronchial tubes and

FIG. 11.—LYMPHADENOMA.  $\times 250$ .

*a.* Fibrous mesh-work (Cornil and Ranvier). *b.* Section of growth.  
*c.* Invasion of muscular tissue by growth.

hepatic ducts), and that hence arises a possibility that, notwithstanding the diffusibility of lymphadenoma, its heterologousness and malignancy may, in the strict sense of these terms, only be apparent. Lymphadenoma not unfrequently affects the bronchial and mediastinal glands; and it may extend thence, along the connective tissue which invests the bronchial tubes, into the substance of the lungs, or may invade the parietes of the heart, insinuating itself between its muscular fibres, without necessarily forming any distinct tumour. The mesenteric glands also are often chief seats of the disease, which is then apt to transgress their limits, to involve the substance of the mesentery, and to creep thence into the intestinal walls, which consequently become thickened in all their

layers, and probably at length present flat tubercular elevations on both the mucous and the serous surfaces. The liver, spleen, and kidneys also are peculiarly liable to suffer. Here, as in the heart, the growth tends rather to infiltrate the tissues than to form defined and independent tumours. In the fresh condition, the affected tracts of these organs present an opaque milky aspect, which may be in striking contrast with that of the surrounding healthy parts; and if they abut on the surface they probably form a slight convexity there. When, however, the contrast of colour has been impaired or lost by maceration, it is sometimes impossible by the naked eye alone to distinguish the healthy from the diseased parts. In the spleen, the microscopical characters of the morbid growth are almost identical with those of the healthy gland-tissue; in the liver and kidneys, however, the growth infiltrates the texture of the organs, and separates their proper elements from one another. In the kidneys especially this may be well observed; for the lymphoid growth spreads through the intertubular tissue of the organ, separating the still healthy tubes and Malpighian bodies from one another, until at length they appear to be sparsely distributed in a nearly homogeneous mass of adventitious cell-growth.

Until recently it was generally held that lymphadenoma was identical with the morbid process affecting the spleen, and occasionally also the lymphatic glands and other organs, in connection with the condition known as leucocythæmia or leukæmia, and was specially characterised by large excess of white corpuscles in the blood. There is reason, however, to believe that this is not the fact; that the morbid processes in the two diseases, though presenting many points of resemblance, are essentially distinct from one another; and that, although in lymphadenoma, as in many other conditions associated with anæmia, the white corpuscles may become relatively increased in number, this excess never approaches that observed in leucocythæmia.

Lymphadenoma is, as has already been observed, a form of malignant disease, which, beginning at one part, generally spreads first to the glands in the neighbourhood, and subsequently to other glands and tissues distributed throughout the organism. The progress of the disease is generally attended with increasing anæmia, and symptoms not unlike those of leucocythæmia; but the development of tumours forms an essential element in the case; and death is likely to ensue ultimately, as in other forms of malignant disease, not merely from gradually increasing debility or intercurrent disorders, but from the involvement in the specific growth of vital or important organs, such as the larynx and trachea, heart, lungs, and abdominal viscera.

Although lymphadenoma is essentially a progressive and incurable disease, and always ultimately fatal, its course is by no means uniformly from bad to worse. In many cases periods of quiescence of longer or shorter duration take place; and in most cases the ordinary course of the disease, which is not necessarily attended with fever, is interrupted (often with some periodicity of recurrence) by febrile attacks of several days'

duration, during which the temperature rises to  $101^{\circ}$ ,  $102^{\circ}$ ,  $103^{\circ}$ , or more, and some of the affected glands (probably a group of glands) become enlarged and tender. With the subsidence of the febrile attacks the tenderness in the glands ceases, and they diminish in size. In most cases, however, a persistent febrile condition of hectic type becomes established sooner or later. The duration of the disease varies between a few months and three or four years.

#### *h.—Sarcomata*

The term 'sarcoma' was formerly applied to all tumours which were supposed to have a fleshy character, and hence came to be used indiscriminately, and to have no precise meaning. It is now, however, limited in its application to those growths which consist, not in their beginnings merely, but throughout the whole term of their existence, of embryonic tissue. Virchow regards them as belonging to the series of connective-tissue tumours which have already been described, and shows that the latter, especially when they undergo generalisation, tend to get more or less obviously sarcomatous—that is, tend to become more and more exclusively cellular, and to lose more and more their several distinctive characters. Sarcoma differs structurally little, if at all, from simple inflammatory granulation-tissue; both of them consist essentially of embryonic cells, which in the first instance are small, round, and separated from one another by the least possible quantity of intercellular substance; in both cases there is a tendency, as organisation proceeds, for the cells to grow fusiform or spindle-shaped while still retaining their embryonic characters; in both cases the anatomical and other features of the new-formed cells are modified, to some extent, according to the nature of the tissues in connection with which they arise; and in both cases the growths become abundantly vascular from the development of new vessels, the parietes of which are formed of cells, little if at all modified from those which constitute the general mass. They differ materially, however, in the fact that inflammatory formations tend to subside or to form mere cicatricial tissue, while sarcomatous tumours maintain a continuous vitality of growth, present a wider range of variations from the primitive type of structure, and are in large proportion malignant.

Many varieties of sarcoma may be described. If it affects a bone, or an osseous tumour, or is attended in its progress with osseous transformation, we have what may be termed an *osteo-sarcoma*; and if, under analogous circumstances, we find sarcomatous growth associated with simple fatty or mucous or gliomatous tissue, we have tumours which may be named respectively *lipomatous sarcoma*, *myxo-sarcoma*, or *glio-sarcoma*. Again, sarcomata may undergo fatty or calcareous degeneration or mucous softening, and hence acquire special characters. The occurrence of degeneration, and especially of mucous softening, often leads to the formation of cysts; and thus arises that variety of sarcoma commonly known as *cysto-sarcoma*.

Sarcomatous tumours are often, and perhaps best, classified according to the characters presented by the cells which predominate in them—the presence of any of the modifications, which have just been indicated, then marking subordinate divisions or varieties. There are at least four such species of sarcoma which we may briefly consider : namely, (i.) round-cell sarcoma ; (ii.) spindle-cell sarcoma ; (iii.) large-cell sarcoma ; and (iv.) melanoid sarcoma.

i. *Round-cell sarcoma*.—In this species the structure of the growth approaches nearest to that of ordinary granulation-tissue—the cells being small, round, distinctly nucleated, and separated by little intercellular substance. Such tumours are nearly homogeneous, but soft and pulpy in texture, greyish or white in hue, opaque or slightly translucent, and (if they have been removed some hours from the body) yield a milky juice. They are very vascular, often attain enormous dimensions, and are malignant in a very high degree. They originate almost indifferently in all parts of the organism, but especially perhaps in the skin and subcutaneous connective tissue, in glandular organs, such as the breast and testicle, in bones and muscles. They comprise most of the tumours which were formerly called ‘medullary sarcoma’ and ‘encephaloid,’ and many of those which were termed ‘fungus hæmatodes.’

ii. *Spindle-cell sarcoma*.—In this case the growth consists of cells which have become elongated and fusiform, or spindle-shaped, and hence present a higher grade of development than those of the round-cell sarcoma. The cells vary a good deal in size, and contain each from one to two or three nuclei. They are arranged side by side in bands or bundles, which take a curvilinear course and cross one another in various directions ; so that, on examining a microscopic section,

FIG. 12.—ROUND-CELLED SARCOMA OF THE LUNG.  $\times 400$ . (Payne).

FIG. 13.—SPINDLE-CELL SARCOMA.  $\times 250$ .

we see round or oval groups of apparently round or oval cells, surrounded by bands of fusiform cells—the former being simply cell-bundles which

have been cut across more or less obliquely. Spindle-cell sarcomata are harder and denser than round-cell sarcomata, greyish or white, slightly translucent, and of a more or less distinctly fibrous or lobulated character. They yield but little juice. They have a tendency to recur, and even to present malignant characters; but their malignancy is far less pronounced than that of round-cell sarcomata, and they rarely reach the size which these latter attain. Spindle-cell sarcoma is synonymous with 'fasciculated sarcoma,' and includes 'Paget's recurrent fibroid tumours.'

iii. *Large-cell sarcoma*.—In some cases the cells of sarcomatous tumours attain unusually large dimensions. The most characteristic example is that furnished by Paget's 'myeloid tumours' of bone. These originate only in bones, destroy them extensively, and grow to a large size. They are made up to a considerable extent of embryonic cells, both of the round and of the spindle-shaped varieties; but what distinguishes them from all other forms of sarcoma is the presence of a greater or less abundance of large cells containing many nuclei. These

cells, which are obviously derived from the many-nucleated cells of the healthy medulla, present much variety. They may measure as much as the hundredth part of an inch in diameter, and thus be objects distinguishable by the naked eye; they may be round or oval, but generally are irregular, and present a more or less complex arrangement of buds or tails; and they may contain any number of nuclei between two or three and two or three hundred. They consist of masses of protoplasm, unbounded by distinct cell-wall, and with the nuclei imbedded in their substance. Although myeloid tumours have unlimited powers of local development, and even invade and grow along the veins, they are rarely malignant in the true sense of that word.

iv. *Melanoid sarcoma*.—In this form of tumour the embryonic cells, which constitute it, are more or less loaded with minute pigment-granules. The cells are round, oval, or fusiform (generally the last), and separated from one another by a small amount of intercellular substance. Each

contains one or two distinct oval nuclei. The pigment-granules are roundish or angular, and separately might pass for oily or cretaceous particles; they are deposited chiefly in the extra-nuclear protoplasm, and sometimes in such abundance that the cell under the microscope appears black, and the nucleus is altogether concealed; but they are found also in the substance of the nucleus. Melanoid sarcomatous tumours are generally soft, and present, if large, a mottled sepia-brown or black appearance; if small, are more or less uniformly tinted. They take their origin almost invariably in structures which normally are pigmented, such as the choroid coat of the eye and congenital pigmented nævi; and when they become generalised, the secondary growths repeat the pigmented character of the primary growth, thus furnishing a good example of the tendency, which secondary growths always have, to reproduce the specific characters of the parent tumour. Melanoid sarcomata are generally highly malignant.

Closely related to the sarcomata, and by Cornil and Ranvier placed among them, is the growth termed by Virchow *psammoma*, which occurs solely in connection with the membranes of the brain and cord. It is vascular, soft, and friable, and chiefly characterised by an abundant development of concentric earthy concretions surrounded with capsules of flattened cells or scales. The type of these tumours is furnished by the choroid plexus. They rarely attain a large size, and probably never cause mischief unless they be large.

#### *i.—Carcinomata, or Cancers*

Cancerous tumours are considered by Virchow to be of a higher type than any which have hitherto been considered. He regards them not as the mere hyperplastic condition of a single structural element, but as consisting of a combination of tissues so arranged as to present some of the distinctive characters of an organ; and he includes them, therefore, in his class of 'organoid tumours.' They are composed of a fibrous framework, or stroma, so arranged as to form a series of loculi, and of groups of cells which are contained in dense masses within them. The stroma consists for the most part of ordinary fibrous tissue and plasmatic cells, and carries and supports the arteries, veins, and capillaries, which are sometimes very abundant; it may be dense or lax, and varies in quantity relatively to the size and number of the spaces which it invests. The loculi differ in size, and on casual examination seem to be round or oval, and unconnected with one another; but, as a rule, they communicate freely, and form a series of branching channels. The cells are said by Virchow, and many others, to be of an epithelial character; and they are so far epithelial that they are developed from the surface of the loculi, are in absolute contact with one another, have no intervening cement, and are never traversed as granulation-tissue is by vessels. They vary greatly in size, and on the average are considerably larger than those of sarcomatous growths. They vary even more remarkably in form, and

indeed their polymorphous character is often regarded as typical of their carcinomatous nature. They may be round or oval, or from mutual pressure polyhedral; but more frequently they are very irregular, presenting convexities or concavities upon their surface, and projecting here and there into flattened, pointed, bulbous, or nondescript processes. They

FIG. 15.—CANCER-CELLS.  $\times 500$ .

consist of masses of protoplasm, more or less granular and often fatty, and containing within them one or more nuclei, which are for the most part round or oval, of comparatively large size and exceedingly well defined. Moreover, they not unfrequently become vacuolated, or hollowed out here and there into globular cavi-

ties which are termed by Virchow 'physaliphores,' and are regarded by him as reproductive cavities. Cancer-cells frequently have a close resemblance to the cells of the vesical epithelium. Cornil and Ranvier deny their true epithelial character, mainly because as a rule they have no distinct cell-wall, and because, although in contact with one another, they generally do not cohere.

The origin of cancers, like that of all tumours in fact, is very obscure. Rindfleisch, taking epithelial cancer as the type, considers that all forms of carcinoma originate in hyperplasia of epithelial structures; which, as they grow, eat their way, as it were, into the subjacent tissues, hollowing them out into irregular cylindrical cavities, which then constitute the characteristic loculi of cancer. This mode of development calls to mind that of tubular glandular organs and hairs in the foetus. Cornil and Ranvier, on the other hand, who expressly exclude epithelioma from true cancers, and consider cancer-cells as being in no sense epithelial, conclude (mainly from their observations on the development of carcinoma in the bones and in the mammary gland) that the alveoli, within which the cells grow and multiply, begin in the plasmatic spaces or serous canaliculi, which are directly continuous with the lymphatic vessels, and that even when they attain their full size they maintain this connection; so that in a sense the alveoli of cancer may be regarded as the dilated origins of lymphatic vessels. To this connection, moreover, they attribute the peculiarly malignant character of all forms of carcinoma. Under any circumstances, however, the early stages of cancer are generally marked by the formation of embryonic tissue: of cells, therefore, differing little from those found in inflammatory processes and in sarcomatous growths. But soon differentiation takes place, and the specific character of the growth is revealed by the conversion of some of these cells into the fibrous tissue of the stroma, and of others of them into the epithelium-like cells of the loculi. There is good reason, nevertheless,

for considering that the matrix in many cases, and in some perhaps almost exclusively, consists of the normal fibrous elements of the part affected, which have simply undergone some degree of thickening and overgrowth ; just as in other cases, where glandular organs are involved, their follicles and ducts may be stimulated to unwonted development, and so form prominent objects in the field of the microscope without necessarily constituting any essential part of the specific growth.

Like other adventitious growths, but in a greater degree than most of them, carcinoma is liable to undergo degenerative changes ; these involve principally the cellular elements, and are sometimes so uniform in their occurrence as to give a special character to the case in which they prevail. Fatty degeneration of cells is the most common ; but we meet also with caseous degeneration, calcareous deposit, and mucous softening ; and not unfrequently extravasation of blood takes place, owing to rupture of the morbid capillary vessels.

All kinds of carcinoma are malignant : the most malignant being the soft or encephaloid form, with its pigmentary and other varieties ; the least malignant being epithelial cancer, which speedily involves the neighbouring lymphatic glands, but is very rarely reproduced in other parts of the system.

The chief varieties of carcinoma are (i.) *Scirrhus* or hard cancer ; (ii.) *Encephaloid* or soft cancer ; (iii.) *Colloid* or mucous cancer ; (iv.) *Epithelioma* or epithelial cancer ; and (v.) *Adenoid* or tubular cancer.

i. *Scirrhus*, in its typical form, is known especially by its hardness and slowness of growth. It creaks on section, and its cut surface presents a white or greyish, glistening, fibrous character, and yields a little milky juice on scraping. Its density and hardness are due to the great abundance and thickness of its fibrous matrix, and to the comparatively small size and number of its cell-containing loculi. The cells, however (which constitute the essential element of the milky juice), present the ordinary characters of cancer-cells. Scirrhus tumours rarely if ever undergo complete cure ; yet it is certain, not only that they are of slow growth, but that their progress is specially apt to be attended with the degeneration (chiefly fatty or caseous) and the subsequent disintegration and removal of the cells of considerable tracts, and

FIG. 16.—SCIRRHUS.  $\times 250$ .

the consequent disappearance from such parts of everything except the fibrous stroma. Scirrhus is equally characterised by the slowness with

FIG. 17.—ENCEPHALOID CANCER.  $\times 250$ .

fact that the fibrous stroma forms a very small proportion of the whole mass, while the cells are relatively very abundant. The alveoli differ in

FIG. 18.—ENCEPHALOID CANCER, FORMING VILLOUS OUTGROWTHS.  $\times 250$ .

size, but are generally comparatively large, and their walls exceedingly delicate; indeed, it is often difficult to recognise the latter at all, unless the cells be first removed by washing or pencilling. In encephaloid cancer, the secondary involvement of the nearest lymphatic glands, and of the general organism, takes place very speedily. Several well-marked varieties of encephaloid cancer are met with, two or three of which may be here enumerated. These are: first, *erectile* or *hæmatoid carcinoma*, in which the vessels (always abundant in encephaloid) are extraordinarily developed and tend to frequent rupture; second, the variety which Cornil and Ranvier term *pultaceous carcinoma*, in which the alveoli are thicker-walled than in most forms of encephaloid, so large that they can easily be recognised by the naked eye, and from which the contents readily escape as a thick pulpy juice; third, *lipomatous carcinoma*, wherein the cancer-cells even from their infancy are loaded with oil, and in the adult state present so general and large an amount of it that, both to the naked eye and under the microscope, the tumour has (at first sight) a considerable resemblance to ordinary fat; fourth, *melanotic carcinoma* in which, as in the corresponding form of sarcoma, the cells are pigmented.

iii. *Colloid cancer* has a close resemblance to myxoma. In both cases the tumours are more or less transparent, and gelatinous in consistence,

which it obviously involves the neighbouring lymphatic glands, and becomes generalised. It invariably, however, sooner or later manifests the infective qualities which belong to it.

ii. *Encephaloid cancer* is soft in texture and rapid in growth, yields a very abundant milky juice, and presents a tolerably uniform opaque white sectional surface, which, however, may be variously studded with patches of congestion or hemorrhage, of fatty or caseous degeneration, or even of pigmentary deposition. Its extreme softness is due to the

fact that the fibrous stroma forms a very small proportion of the whole mass, while the cells are relatively very abundant. The alveoli differ in size, but are generally comparatively large, and their walls exceedingly delicate; indeed, it is often difficult to recognise the latter at all, unless the cells be first removed by washing or pencilling. In encephaloid cancer, the secondary involvement of the nearest lymphatic glands, and of the general organism, takes place very speedily.

Several well-marked varieties of encephaloid cancer are met with, two or three of which may be here enumerated. These are: first, *erectile* or *hæmatoid carcinoma*, in which the vessels (always abundant in encephaloid) are extraordinarily developed

and in both yield from the cut surface an abundant juice, which is transparent, glairy, and characterised by containing mucine. The fundamental anatomical distinction between them is this,—that, whereas in myxoma the framework of the tumour consists of plasmatic cells, the mucous fluid and vessels occupying the interstices between them, in colloid carcinoma the mucus arises in the degeneration of the essential cells of the growth, the general solidity of the tumour being due to the fibrous stroma, which forms the walls of the alveoli. In colloid cancer the alveolar structure is extremely well marked, and on this account colloid has often been termed ‘alveolar cancer.’ The alveoli are so large as to be easily visible to the naked eye; they are round or oval on section; and when the growth forms a projecting mass on a serous surface, their aggregation presents the appearance of an accumulation of small bubbles of air in a viscid fluid. They communicate freely with one another. Their walls are

FIG. 19.—COLLOID CANCER.

*a.* Fibrous stroma.  $\times 250$ . *b.* Cells, degenerating.  $\times 250$ .

mostly extremely thin and delicate, displaying a fibrillated structure with an indistinct development of fusiform cells, which may themselves present indications of fatty or colloid degeneration. The glairy contents of the alveoli vary, from the consistence of white of egg up to that of pretty firm glue, from pure white to a more or less deep yellowish, brownish, or reddish hue, and from perfect transparency to tolerably complete opacity. Microscopically, cancer-cells can always be recognised. The smaller alveoli of the newly developed parts are probably full of well-defined cells, of which some already contain globules of mucus. As, however, the growth gets older and the alveoli larger, the cells undergo more and more complete mucous degeneration, swell up, and presently disintegrate; and thus in many cases the alveoli get distended with mucus, presenting a certain amount of granular matter, mostly arranged in irregularly concentric circles, with here and there perhaps the ghost of a huge dropsical cell. In addition to the mucous conversion, which is the especial feature of

colloid cancer, a certain amount of fatty degeneration is common. Calcareous deposition also is not unfrequent.

Although colloid cancer is certainly malignant, and affects lymphatic glands, and occasionally becomes generalised, it is specially characterised by a tendency to spread in area, and to implicate the tissues immediately subjacent to that area. Thus, when arising in the peritoneum, it soon diffuses itself over the greater part of that membrane, and also soon involves, in many situations, the whole thickness of the stomachal or intestinal walls. It shows also (though it is not peculiar in this respect) an obvious proneness to spread along the lines of the lymphatic canals and capillaries.

iv. *Epithelioma*, or canceroid, is a very characteristic form of growth, originating, but not quite exclusively, in epithelial tissue, and characterised

FIG. 20.—EPITHELIOMA.

a. Section of growth.  $\times 250$ . b. Free cells.  $\times 250$ . c. Free cells more highly magnified.  $\times 500$ .

by a very abundant formation of epithelium in cavities or loculi of considerable size, which, as in other forms of carcinoma, communicate more or less freely with one another.

The commonest form of epithelioma is that which arises in the skin, and those mucous surfaces which are in relation with the external orifices, namely, those of the lips, tongue, œsophagus, anus, vagina, and uterus. It forms a tumour which varies in size, soon ulcerates, and on section presents (owing partly to the fact that the tissues which it invades are not yet wholly destroyed by it) a more or less variegated character; it is friable in texture, somewhat granular, and yields on pressure or scraping, not a juice, but rather an opaque, whitish, granular pulp. The stroma of the growth consists of fibrous or embryonic tissue, including vessels, and more or less abundant traces of the original healthy structures. The pulp which exudes, and the contents of the loculi, consist solely of cells in different stages of development. These are distinctly nucleated, modified in shape

by mutual pressure, and for the most part large and strikingly epithelial in character. The younger cells are in relation with the stroma, and occupy therefore while *in situ* the periphery of each cell-mass; the others are arranged in a more or less stratified or confused manner within. But we find additionally, in the latter situation, knots or nests or involucri of cells the presence of which is almost conclusive as to the nature of the growth. These consist of large flat cells, arranged in concentric circles around a group of cells, or even a single cell, of smaller size, of plumper form, thick-walled, and containing a nucleus, together with perhaps some mucous or colloid material, or a few small fat-globules. At first sight, these nests look not unlike transverse sections of cutaneous papillæ, but they obviously differ from them in the fact that their centres are made up simply of cells, and not of stroma containing vessels.

[As regards the development of epithelioma, there is little doubt that when it occurs at epithelial surfaces, it commences with hyperplasia of the deeper-seated embryonic cells of epithelium:—in the skin, therefore, with hyperplasia of the cells of the rete mucosum and of the sebaceous and sudoriparous glands; in the mucous membranes, with hyperplasia of the corresponding cells of their epithelium, and of the glandular crypts. These multiply, become modified in form and arrangement, distend the cavities or depressions in which they lie, and send thence into the immediately surrounding tissues bud-like processes. The latter increase in number and size, and thus gradually invade and destroy the neighbouring textures. Rindfleisch quotes an observation, and reproduces a drawing of Köster's, which seem to show that the extension of epithelioma is due to the involvement of the lymphatic networks: that the budding or sprouting

FIG. 21. ADENOID CANCER FROM LIVER.  $\times 250$ .

epithelial processes above adverted to, instead of forming indiscriminately, penetrate the capillary lymphatics, run along them and distend them. There is probably some truth in this view; and, if so, it assimilates the local spread of epithelioma to that of colloid cancer, and especially to that of scirrhus and encephaloid cancer, as described by Cornil and Ranvier.

Epithelial cancer is undoubtedly the least malignant of all the varieties of carcinoma ; for it is the only cancer which admits of being removed in its early stage with the tolerable certainty that it will not recur ; and although it soon involves neighbouring lymphatic glands, it rarely manifests itself secondarily in other internal organs.

v. *Adenoid or tubular cancer*, otherwise termed columnar or cylindrical epithelioma, is a rare affection, said generally to originate on some mucous surface, and to involve secondarily lymphatic glands and other parts. It occasionally, however, arises primarily in the liver or other parenchymatous organs. It forms tumours of various sizes, which have a close general resemblance to those of encephaloid cancer. They are highly vascular, soft, and yield an abundant milky juice. Microscopically, they are seen to consist of a system of tubules irregularly arranged, and separated from one another by a very small quantity of fibrous stroma ; and bear a striking resemblance to sections of the cortical substance of the kidney deprived of Malpighian bodies. The tubules are generally cylindrical, of tolerably uniform size, and lined with a layer (usually single) of spheroidal or columnar epithelium. They present, for the most part, a distinct central cavity or canal. This form of carcinoma is highly malignant.

#### *j.—Granulomata or Granulation Tumours*

The term ‘granuloma’ has been employed by Virchow to include the specific growths of syphilis, lupus, elephantiasis Græcorum, and farcy, because anatomically they differ but little from ordinary granulation-tissue, and it is often difficult to decide from mere inspection whether such growths are tumours or mere inflammatory products. Tubercle he regards as a species of lymphoma. There is no doubt, however, that tubercle has close structural relations to the specific growths of the other affections above named. And since, moreover, they are all infective growths, and there is reason to assume, from recent observations, that the specific causes of most, if not all, of them are parasitic organisms, we have included them all in the same group. As we shall presently show, a specific bacillus has apparently been proved to be the cause of tubercle. It is alleged also that specific bacilli have been discovered both in syphilis and in leprosy.

i. *Tubercle*.—From the time of Laennec down to within a very recent period, tubercle was regarded as a mere exudation or deposit from the blood, consisting in large measure no doubt of cells, but of cells which were degenerate from the beginning and never had any vitality. And it was recognised as occurring in two forms : one, the grey granulations or miliary tubercles (hard, greyish, translucent bodies, varying from the size of a small pea downwards, and tending to become opaque, yellow, and soft or friable internally) ; the other, the so-called ‘crude’ tubercles, which are generally of larger size, of a nearly uniform opaque buff colour, and friable or cheese-like in consistence, but which were commonly believed to take their origin in the general caseous conversion of grey tubercles, and therefore to represent a comparatively late stage of the

tubercular process. It is now, however, generally admitted: that tubercle is no mere deposit, but on the contrary, equally with sarcoma and carcinoma, a living growth, consisting essentially of cells, but having, above all other growths, a tendency to undergo rapid degeneration and death, and especially that form of degeneration which is termed 'caseation'; that the grey semi-transparent material which often forms the whole bulk of miliary granulations, and may often be recognised at the periphery of larger masses, is alone living and growing tubercle; and that the yellow caseous substance which has frequently been taken for its essential part is merely effete and dead matter, often no doubt tubercular in its origin, but often also the detritus of quite other kinds of cell-growth.

Grey granulations take their rise in the connective web of most organs and of many tissues, and, as will presently be shown, not improbably affect specially the lymphatic tissue distributed throughout the organism. They are common in serous membranes and in the pia mater, and it is probably here that their development may best be studied. If a minute

FIG. 22.—TUBERCLE. (Virchow.)

tubercle from one of these situations be placed under the microscope, it will be found to consist mainly of an aggregation of cells, mostly of small size and of the embryonic character, of which those towards the centre will probably even now be angular, withered, and opaque from granular fatty deposit. A close examination will reveal other facts:—the growth will be found almost certainly to have taken place in connection with some minute vessel, probably to encircle it; and further, beyond the margins of what may perhaps be regarded as the actual growth, a zone of connective tissue will be recognised in which apparently hypertrophy and proliferation are commencing—the plasmatic cells being larger than those of the normal tissue, and in many instances containing in their interior broods of two, three, or more secondary cells. It would seem, therefore, that the morbid process commences with proliferation in or among the connective-tissue elements of the adventitia or outer wall of blood-vessels, that it gradually involves more and more of the neighbouring connective tissue, and that as it spreads at the margins the central parts fall rapidly into decay. It follows that the chief microscopic elements of tubercle are: first, simply enlarged connective-tissue corpuscles (fusiform and stellate); second, these same cells containing two or more new cells

within them; and third (and probably far most abundantly), small shrivelled granular embryonic corpuscles. But during the last few years it has been distinctly ascertained that, although neither peculiar to tubercle nor essential to it, certain cells presenting remarkable characters are commonly to be found, either in the centre of elementary tubercles, or distributed in the peripheral parts of agglomerated tubercles. These are large irregular branching bodies, termed 'giant cells,' of which each contains from twenty to forty distinct nuclei. Their source is not clearly determined. In some cases possibly they result from the fusion of smaller cells; but Brodowsky has shown it to be probable that, at any rate, some of them are to be regarded as morbid modifications of protoplasmic buds from the walls of vessels, which, under other circumstances, would have become vessels. It should be added, that new blood-vessels seem never to form in the tubercular process; that no higher stage of development,

FIG. 23.—TUBERCLE, SHOWING *g*, GIANT CELLS WITH PROLONGATIONS, AND *e*, EPITHELIOID CELLS (Payne).

in fact, than the mere over-production of new cells of a low grade of organisation is ever attained; and further, that the vessels around which tubercles form become at a very early period obstructed by the coagulation of fibrine, and the accumulation of leucocytes, in their interior. The intercellular substance of tubercle is, in the first instance, that of the particular form of connective tissue in which it originates; it soon, however, gets scanty and indistinctly fibrous or granular. Rindfleisch has described a reticulated connective tissue, in the meshes of which the corpuscular elements are contained: an arrangement, in fact, almost identical with that which obtains in adenoid tissue, and which, if generally present, goes far to confirm the views of those who regard tubercle as an adenoid growth. It is extremely difficult, however, to satisfy oneself of the presence of any such fibrous stroma, and Cornil and Ranvier distinctly deny it. They admit that a kind of reticulum, probably of artificial production, may be recognised in sections which have been hardened with chromic acid or alcohol; but they assert that it never contains protoplasmic

particles (as lymphatic stroma does) at the points where the fibres intersect, and moreover that in the unprepared tubercle it has no visible existence.

But even if tubercular growths be not, like lymphadenomatous tumours, mere overgrowths or reproductions of modified lymphatic-gland structure, there can be no doubt at all that they are in very large proportion adventitious growths originating in lymphoid tissue. At all events, many physiologists, and particularly Sanderson, have shown that adenoid tissue is far more generally distributed throughout the body than was formerly suspected, and that it is especially abundant in all those parts in which tubercle is most frequently developed; and indeed, as regards tubercles produced experimentally, Sanderson seems to have clearly demonstrated their origin in hyperplasia of these normal lymphatic accumulations. We need hardly quote, in favour of this doctrine, the fact of the frequent development of tubercle in the lymphatic tissue of the solitary and agminated glands of the intestines, and in that of the spleen and lymphatic glands. We will discuss two cases, however, which Sanderson has specially investigated in the course of his experiments on the artificial production of tubercle. In the first place, he has shown that in the peritoneum, as indeed in all serous membranes, small masses of adenoid tissue are distributed abundantly, in some cases unconnected with vessels, but more commonly adherent to their walls, or encircling them, or even investing whole groups of capillary vessels; he has also shown that, in animals dead of acute peritonitis, all these masses have become soft, tumid, and enlarged, and further that, when tuberculosis is in progress, it is in them and by the multiplication of their cells, rather than by that of connective-tissue corpuscles, that miliary tubercles are gradually developed. Secondly, as regards the lung, it is now generally held that grey tubercles originate in the matrix of the organ, and not, as was formerly believed, within the air-cells; and it is generally admitted, we believe, that the part which they chiefly affect is the connective tissue surrounding the bronchioles at the point at which these lose themselves in the air-cells, and that the growth of tubercle-cells gradually extends thence into the tissue which separates the air-cells from one another, and limits each pulmonary lobule. Now, according to Sanderson, there always are normally, in the situation here indicated, masses of adenoid tissue, and the early stage of pulmonary tuberculosis consists in a kind of hyperplasia of such masses.

The frequent connection between tubercle and adenoid tissue must be admitted. Nevertheless it is certain that, like lymphadenoma, tubercle does not take its origin exclusively in adenoid tissue. The general result, deducible from recent observations with respect to the genesis of tubercular products, seems to be that, like the products of inflammation, they are not derived from a single source, that they are not the results of specific hyperplasia of connective-tissue corpuscles alone, as Virchow teaches, nor yet simply overgrowth of the lymphatic cells of adenoid tissue, but that they are probably derived, in varying proportions, from both

of these sources, from the other cellular elements which happen to form part of the affected tissue, and even from immigrant leucocytes.

The view here expressed has an important bearing on the question 'what is and what is not to be regarded as tubercle?'—a question of the highest interest, in reference to the status of the morbid condition of lung commonly known as 'pulmonary phthisis,' and to the nature of closely related, if not identical, morbid conditions of other organs. According to views generally accepted until within the last few years, the grey miliary tubercle and the yellow cheesy tubercle (of which both are common in the lungs, and the latter occasionally, by coalescence, infiltrates large tracts) were regarded as being, not so much varieties, as different stages of the same disease; and it was held that, in the dead-house, all the intermediate conditions, by which the minutest miliary tubercles lead up to the most extensive caseous infiltration, can be readily recognised. At the present day, Virchow and many other distinguished pathologists deny this relation, and maintain that caseous disease, which comprises probably all the cases recognised clinically as pulmonary phthisis, is of pneumonic origin, the consequence of catarrhal or lobular pneumonia. The grounds of this opinion are mainly, that in caseous infiltration of the lung the presence of tubercular proliferation of the interstitial tissue is not a very obvious anatomical feature; and that the great bulk of the morbid mass consists of degenerate epithelial cells accumulated in the air-cells and smallest bronchial passages. Many important considerations, however, may be adduced in favour of the opposite view. It is a fully recognised fact that, even in undoubted examples of miliary tubercles, the proliferation of cells in the matrix of the pulmonary lobules, which constitutes their commencement, is soon attended with dense accumulation of cells, probably due to epithelial proliferation, within the pulmonary loculi. Now, unless we start with the assumption that tuberculosis consists in nothing else than proliferation of connective-tissue corpuscles, or of the elements of adenoid tissue, what right have we to assume that the protoplasmic bodies, which fill the air-cells, are specifically different from those which occupy the substance of the matrix? It is admitted that pus-cells may originate in epithelial as well as in other kinds of cells; why should tubercle-cells have a more exclusive parentage? It is a recognised characteristic of tubercle that its specific cells very rapidly fall into degeneration; but this is even more remarkable in the cells which fill the loculi, than in those which crowd the pulmonary matrix. Again the caseous masses of pulmonary phthisis certainly do not occupy those parts of the lung which either lobular or lobar pneumonia specially affects; but they do occupy those situations (mainly the upper portions of the lungs) in which miliary tubercles generally originate, and are most advanced. And, lastly, caseous tubercles in the lungs are constantly associated with tubercular formations elsewhere in the body, and indeed in those very parts in which generalised miliary tubercles are specially apt to manifest themselves. For many reasons, therefore, of which we have only indicated the more important, we are disposed to maintain the

relationship between miliary tubercles and caseous infiltration, to regard them simply as varieties or different stages of the same disease, and to support the claim of 'pulmonary phthisis' or 'caseous pneumonia' to be called also 'tubercular phthisis.'

The investigations of Klein<sup>1</sup> and Charcot<sup>2</sup> are strongly confirmatory of the views here advocated. Klein shows: that in miliary tubercles of the human lung, 'the first change takes place in the alveoli and inter-alveolar septa;' that, as regards the alveoli, the epithelial cells become swollen, granular, and detached, that they then proliferate, and that generally, either by their coalescence or by the disproportionate enlargement of one or more of them, each cavity becomes filled with a multinuclear lump of protoplasm or giant cell, which subsequently undergoes fibrillation, caseation, or other form of degenerative change; and that, as regards the inter-alveolar septa, these thicken with the growth of a tissue containing branched and spindle-shaped cells and a few lymphoid cells. He adds that, at a somewhat later period, cords of adenoid tissue are formed upon the walls of the larger vessels in the vicinity of the tubercles. He further points out, in reference to tuberculosis of artificial production, that, although the ultimate changes are identical with those just described they take place in an inverse order, the development of the perivascular adenoid cords preceding the changes in the inter-alveolar septa and in the air-cells; and he concludes that, in artificial tuberculosis, the process commences from the arteries and veins, in the idiopathic affection from the pulmonary capillaries. Charcot's observations are still more to the point, for he expressly shows that there is no essential, genetical or structural, difference between miliary tubercles of the lungs and so-called 'caseous pneumonia.' He points out, however, that in the latter variety of pulmonary phthisis the tubercular process commences in the *parietes of the bronchioles*, where these lose themselves in the air-cells; that softening takes place here before any trace of inflammation is visible either in the epithelial lining of the tubes or in the pulmonary lobules connected with them; and that, when a caseous patch is examined, it presents a central degenerate area, and a marginal zone of embryonic cells, and scattered giant-cells, infiltrating the normal tissues of the lung.

The quasi-malignant character of tubercle is generally admitted; although the fact, that it appears often to originate, almost simultaneously, in many points of one or more organs (in both lungs, for example), might seem to imply the existence, in some cases, of a widely diffused tendency of organs to become tubercular, independently of specific infection. The proof of its malignant attributes lies, partly in that disposition to general diffusion which it shares with growths which are unquestionably malignant; and partly in the facts, that its local spread is due chiefly to the establishment of new foci of disease in clusters around the primary growths, and that the nearest lymphatic glands always become secondarily

<sup>1</sup> 'On the Relation of the Lymphatic System to Tubercle.' *Report of the Medical Officer of the Privy Council*. New Series, No. 3, 1874.

<sup>2</sup> *Revue Mensuelle de Médecine et de Chirurgie*, 1877, p. 876.

affected at an early period. It was considered by Laennec (and his view in a very slightly modified form has been advocated by Dittrich and Niemeyer) that a degenerate mass of tubercle (a caseous lymphatic gland, for example) is a common, if not the invariable, source of generalised tuberculosis: that the degenerate particles taken up by the blood become distributed by it, and then act as specific irritants to the parts which they infect.

The remarkable experiments, in reference to the production of tubercle by inoculation, first made by Villemin, and since repeated and extended by Wilson Fox, Sanderson, Cohnheim, and others, have a very interesting bearing on the points considered in the last paragraph. Guinea-pigs and rabbits were inoculated with tubercular matter; and it was found that, after the lapse of some weeks, small indurated caseous nodules had become developed at the seat of operation, the next lymphatic glands had undergone hyperplastic enlargement, and the lungs, liver, serous membranes, and some other organs presented a greater or less number of small, grey, translucent, hard bodies, which accurately resembled the miliary tubercles occurring in man; and it was assumed that all these secondary formations were really tubercle, and that tubercular detritus taken up by the absorbents, and then distributed throughout the organism, had a specific influence in the production of tubercle. It was soon proved, however, that the inoculation of other forms of growth, or of decomposing healthy tissue, or of the products of local inflammations excited by mere mechanical irritants, was quite as efficient in generating general tuberculosis, as was the inoculation of tubercular matter itself. And hence it seemed obvious, that the exciting cause of the tubercular development was, not the matter which was inserted or applied locally, but the products of the inflammatory process which this matter evoked. The experiments failed, therefore, to prove the inoculability of tubercle, but they proved that tubercle might be produced locally by direct apparently non-specific irritation, and that tubercle so engendered had the capacity for becoming generalised. To a certain extent, then, these experiments may seem to favour the views of Laennec and Niemeyer as to the infective quality of caseous matter. It is more in accordance, however, with what is known of morbid proliferation, and of contagion, to assume that the infective element of tubercle is not effete and dead material, but rather living (even though degenerating) particles of protoplasm.

There has long been a suspicion amongst pathologists, that tubercle, and other allied infective diseases, are determined by the presence of specific parasites, as we have already shown is probably the case with spreading and infective inflammations; and many observers have laboured with the object of finding them. But their labours were fruitless, until Dr. Koch, the foremost and most successful worker in this branch of investigation, succeeded by special methods of preparation in discovering, early in 1882, the presence of apparently specific bacteria in tubercle. These are minute motionless rod-like bodies, from a quarter to half the diameter of a blood-corpuscle in length, presenting no marked morphological characters, but differing from the known forms of bacteria (excepting perhaps those

found in leprosy) in the effects upon them of certain dyes. They have been found in more or less abundance, not only by Koch himself, but subsequently by many other observers, in all tubercles, in whatever part of the body occurring, and as well in the tuberculosis of the lower animals as in that of man. They are said to abound chiefly in recent tubercles and in the periphery of tubercular aggregates, and specially to affect the giant-cells; and to be comparatively few in number, or absent, in parts which have undergone degeneration. Moreover they are found in more or less abundance in the sputa of phthisical patients, especially in the sputa of those cases in which rapid disorganisation of lung-tissue is taking place; and are said never to be present in the sputa of non-tuberculous patients. This statement, if true (and it accords with our own limited experience), makes the examination of the sputa for the bacilli important for the determination of the nature of obscure cases of lung-disease, and makes it important, therefore, that the methods by which they may be rendered visible should be well understood and easy of application.

But Koch's researches have not been limited to the discovery of the bacilli of tubercle in tubercular growths. For by carefully devised methods of procedure he claims to have cultivated them, external to the body and apart from tubercular matter, in suitable cultivation media; and then to have developed tuberculosis in guinea-pigs and rabbits by inoculating them with the organisms thus grown. The bacilli require for their cultivation the maintenance of a temperature about equal to that of the human body.

It is scarcely justifiable perhaps to assert at the present time that the bacilli discovered in tubercle have been absolutely proved to be the cause of tubercle. But it must be admitted that the evidence in favour of that view is very strong. Nor, even if this relationship be established, does it necessarily follow that tubercle is an infectious disease any more than ague is infectious. Still the probability of its direct or indirect infectiousness becomes much increased. We believe the bacilli found in tubercle are the cause of tubercle, and that the disease is infectious. The parasitic origin of carcinoma remains to be discovered.

It is important to observe that the tubercle bacillus is found equally in grey miliary tubercles and in so-called 'caseous pneumonia'; and that its discovery tends therefore to confirm the views previously expressed in regard to the identity of the different varieties of pulmonary phthisis.

For the clinical detection of the tubercular bacillus, Gibbes's rapid double-staining method is convenient and trustworthy.

Put a little suspected sputum or other fluid between two cover-glasses

FIG. 24.—BACILLI OF TUBERCLE FROM SPUTUM.  $\times 500$ .

and rub them together. Separate them; dry them in the air; pass them, thus prepared, three or four times through a spirit-lamp flame in order to fix the material; and float them (preparation-side downwards) on the staining fluid. After they have been allowed to remain thus for a sufficient length of time (five minutes if the solution be used warm, but one hour if it be used cold), they are to be removed, washed in methylated spirit till no more colour comes away, dried in the air or over a spirit lamp, and then mounted in Canada balsam.

Gibbes's solution is prepared as follows:—First, triturate two parts of rosaniline hydrochlorate, and one part of methylene blue in a glass mortar; second, dissolve three parts of aniline oil in fifteen parts of rectified spirit, and add the mixture slowly to the former; lastly, add slowly fifteen parts of distilled water. Keep in a stoppered bottle.

The most common seats of tubercle are the lungs and the mucous membrane of the intestines. But tubercles are generally largely distributed throughout the bodies of those who die tuberculous; and we may enumerate as their seats of election, after the lungs and bowels, the serous membranes, the spleen, the kidneys and liver, the brain and its membranes, the mucous surface of the genito-urinary organs, the suprarenal capsules and the bones, and of course the lymphatic glands.

FIG. 25.—SYPHILITIC GUMMA FROM HEART.  $\times 250$ .

ii. *Syphilitic gummata* have a close anatomical affinity with tubercle on the one hand, and with inflammatory products on the other. They resemble granulation-tissue

in the general character and arrangement of their cellular structure, and in the facts that they are provided with permeable vessels, and at an early period of their growth are capable of conversion into cicatricial tissue. They tend, however, like tubercles, to undergo early caseation and death; and, if their progress be not modified by medical treatment, this may be regarded as their normal termination. It is in this latter condition that they are almost invariably found post mortem in the liver, testicles, brain, bones, and other internal organs. They then form opaque, buff-coloured, toughish masses, imbedded in dense connective or cicatricial tissue. They are especially common in the skin and subcutaneous connective tissue, but here they generally undergo ulceration and leave indelible cicatrices. Excepting by their toughness, by the size which they attain, and by the paucity of their numbers, it is exceedingly difficult to distinguish caseous gummata from tubercles in the same condition. In the brain and testicles especially, the resemblance between gummata and tubercles is remarkably close.

## B. ATROPHY, DEGENERATION, AND NECROSIS

1. *Atrophy and Degeneration*

THE term 'atrophy' means strictly mere diminution in the bulk of tissue from deficient nourishment. The term 'degeneration,' on the other hand, implies degradation of tissue—in other words, a qualitative rather than a quantitative change. A part which suffers atrophy simply wastes, while one which undergoes degeneration often presents an actual increase in bulk. Yet, though atrophy and degeneration imply, so to speak, different lines of decay, they are so constantly associated that, in a practical sense, they scarcely admit of separation.

When degeneration is in progress, we find that the microscopic structure of the parts involved gradually becomes confused and destroyed, and that accompanying this process fat, pigment, or other matters, which normally have no visible existence in them, are deposited in a globular or granular form. Whence do these matters come? Are they due simply to the decomposition of the highly organised material which is undergoing degeneration, and to the precipitation of its more insoluble constituents, or do the decaying tissues attract them to themselves from the blood or extra-vascular nutrient fluid? There can be no doubt that both of these processes take place; and that, although they are distinct and not unfrequently dissociated, they generally concur. In most cases, where degenerative products are visible, they are due partly to simple precipitation, partly to infiltration.

It will thus be understood that degeneration, in its widest sense, involves three processes which are essentially distinct from one another:—namely, first, simple atrophy or wasting of tissue, second, degeneration proper, or the decomposition of tissue, and, third, the deposition in the affected parts of insoluble matters derived from without; and that these processes are generally associated, although in very various proportions. It should be added that the visible products of degeneration are only the more insoluble products of these processes; and that other effete or degraded matters are produced simultaneously, which are probably just as important, although more difficult to recognise, partly on account of their solubility, partly because they assume no crystalline, molecular, or other visible form. We shall discuss the generally recognised varieties of degeneration *seriatim*.

*a. Cloudy Swelling.*—When cells are exposed to the direct influence of certain poisonous substances, or when they soak in the dropsical or inflammatory fluids which escape from the blood, they often get distended from imbibition, and at the same time their protoplasm acquires a finely granular character. The same changes, according to Cornil and Ranvier, take place in the nuclei and nucleoli. Virchow regarded them as the result of nutritive irritation. But they are now generally admitted to be of a degenerative nature, or at all events passive, and in many cases a first step towards fatty degeneration. The granules, however, are not fatty

but albuminous, and readily dissolve in acetic acid. Cloudy swelling is well shown by the hepatic cells in cases of acute atrophy of the liver.

*b. Mucous and Colloid Degenerations.*—In many cases cells, and in some instances intercellular substances, undergo softening and conversion into matters which are known as ‘mucus’ and ‘colloid.’ These may form a thin glairy fluid, or present all degrees of viscosity between this and a thick jelly; and may be transparent and colourless, or of different tints of yellow, brown, or red. They have, therefore, a very close resemblance to one another; and, indeed, are not always easy to distinguish. They differ chemically in the fact that mucus contains mucine in solution—a substance precipitable by acetic acid; while the specific element of colloid is an albuminous substance which is not affected by this reagent.

*Mucous degeneration* involves sometimes the intercellular parts of tissues, sometimes the cellular elements. Of the former case we have examples in the mucous softening which takes place in the matrix of enchondromata and of the cartilages of elderly persons, and perhaps also in myxomatous tumours. The latter case is exemplified in the formation of globules of mucus within the cells of mucous membranes, the consequent distension of the cells, and their final deliquescence. Mucous degeneration is common in the cells of synovial and mucous surfaces; it is a characteristic feature of the progress of colloid cancer; and it is not unfrequent in other morbid growths—leading to the formation of cysts.

*Colloid matter* is most frequently met with in the cysts of the thyroid body, and in small renal cysts; and, like mucus, generally arises within cells, which it presently fills and destroys. In the cases just referred to, it forms rounded jelly or glue-like masses filling the cavities, and containing imbedded in them the remains of the cells which gave them origin. It seems probable that the glassy transformation of voluntary muscles in typhoid fever described by Zenker (and which is marked by a peculiar waxy lustre, the disappearance of the normal markings, and a tendency to crack transversely) is really an example of colloid degeneration. Further, there is reason to believe that many so-called ‘fibrinous’ casts of the urinary tubules are rather colloid matter than fibrine.

FIG. 26.—COLLOID DEGENERATION OF MUSCLE.  $\times 250$ .

*c. Lardaceous Degeneration*, known also as ‘waxy,’ ‘bacony,’ ‘albuminoid,’ ‘amyloid,’ and ‘scrofulous’ degeneration, has (as the many names which have been applied to it testify) long been recognised, and presents many remarkable characteristics. It occurs almost exclusively in cases of tertiary syphilis, chronic phthisis, and long-continued suppuration, especially in connection with bone disease; and indeed, since prolonged suppuration is constantly associated with both chronic phthisis and the later stages of syphilis, there is some reason to regard the lardaceous change as the consequence essentially of suppuration. It

affects mainly the liver, spleen, and kidneys; which increase slowly to many times their original bulk, grow dense and homogeneous in texture and doughy in consistence, and present when cut a pale brownish tint, with a slight degree of transparency and a peculiar waxy lustre. Microscopically, the change is found to be due to the infiltration of the walls of capillary and other small vessels, of the walls of ducts, and of the substance of cells, with a transparent, colourless, refractive material; which by its presence obliterates all their structural characteristics, gives them a jelly-like or vitreous aspect, and converts the vascular and duct walls into thick homogeneous hollow cylinders, and the cells, with their nuclei, into amorphous masses, with a tendency to irregular fracture. The microscopical appearances of parts which have undergone lardaceous

FIG. 27. —LARDACEOUS DEGENERATION OF KIDNEY.  
*a.* Malpighian body and afferent vessel.  $\times 250$ . *b.* Section of tubes of medulla.  $\times 250$ .

infiltration are not altogether unlike those displayed by structures which are the seat of mucous or colloid change; but lardaceous matter is tougher and more consistent than mucus and colloid generally are, it invades structures which these latter never affect, and moreover never leads to the deliquescence and utter destruction of tissues. The chemical characteristics of lardaceous matter are of considerable interest. Virchow some years ago, finding, as he thought, that on the addition of sulphuric acid and iodine it assumed a blue tint, concluded that it was identical with the cellulose of plants, which under the influence of the same reagents becomes first converted into starch and then blue; and hence he gave it the name of 'amyloid matter'—a name by which it is still largely known, although the theory which gave it origin is now only

matter of history. It has been conclusively shown, indeed, that lardaceous matter has no sort of chemical relation with starch or cellulose, and that the addition of sulphuric acid and iodine produces a bluish tint only in consequence of the precipitation of the iodine in a molecular form. Lardaceous matter, in fact, is a modification of albumen, with a deficiency of potash and phosphoric acid, but with an excess of soda, hydrochloric acid, and especially cholesterine; and it is easily recognised by its rapid absorption of iodine even when this is applied in the form of a very weak solution, and its consequent acquisition of a peculiar and very characteristic reddish-brown or mahogany tint. Dr. Dickinson has pointed out, as an equally valuable test, the readiness with which it is stained blue by solution of sulphate of indigo.

Lardaceous degeneration of organs, unless it becomes extreme, does not necessarily impair their functional activity. Its effects in this direction only show themselves late in the progress of the disease, and are then probably due in great measure to pressure and other simple mechanical causes.

Although occurring most frequently and obviously in the organs which have been named, lardaceous infiltration occurs also in other parts of the organism. Thus, it is not uncommon in the villi of the intestine and the mesenteric glands; and the so-called 'corpora amylacea' of the nervous centres not only have microscopic characters resembling those of some forms of starch, but present the same chemical reactions as lardaceous matter occurring in other organs.

*d. Fatty Degeneration.*—Three different conditions are not unfrequently included in this term; namely, first, the overgrowth of fatty tissue; second, the superabundant storage of oil in cells (other than fat-cells) which are apt to contain normally a greater or lesser quantity of oil; and, third, the actual degeneration or decay of tissue, attended with the appearance of molecules of oil in its substance. It is obvious that the first of these conditions is not a degeneration in any sense of the word. No doubt in many cases, as when it affects the heart, it impairs functional activity, but it impairs it by its mechanical influence only. Again, the second condition cannot properly be regarded as a degeneration. It is observed most characteristically in the so-called 'fatty degeneration' of the liver, where the organ increases in size, gets paler and softer than natural, and greasy, and is found under the microscope to have its constituent cells distended with accumulated oil-drops. But under normal circumstances the liver-cells contain a variable amount of fat. The presence of fat in them, therefore, is no sign that they are degenerate; and moreover its excessive accumulation does not lead to their destruction, nor does it (according to our experience) affect injuriously the performance of the hepatic functions. The third of the above conditions alone merits the name of fatty degeneration.

*Fatty degeneration* commences almost invariably in cells or other forms of protoplasm, which get studded with minute refractive molecules, and at the same time increase in bulk. These molecules are supposed to

be derived mainly, if not exclusively, from the degradation or decomposition of the protoplasmic matter itself, and are at first few in number and small in size, and chiefly collected immediately around the nucleus. Gradually they increase in number and size, concealing the nucleus and distending the cell, which then acquires a round or oval figure, and appears by transmitted light as an opaque black granular mass, constituting what is generally known as a 'granule-cell,' and has been sometimes termed an 'inflammatory corpuscle.' The last stage is represented by the further enlargement of the cell, its rarefaction, and final deliquescence, with the setting free of the fat-granules which had been imbedded in it. In the later phases of fatty degeneration, when the cells are in great measure destroyed, and the oily matter is diffused throughout the tissues, cholesterine, which had doubtless been suspended in the oily molecules, separates from them, and appears amongst them in the characteristic form of incomplete rhomboidal plates; and the whole tissue gets confused, softened, and reduced to an opaque yellowish-white pulp, or 'detritus.'

FIG. 28.—CHOLESTERINE.  $\times 250$ .

The process above described is common in nearly all vital tissues.

FIG. 29. —FATTY DEGENERATION.

- |     |   |  |

| a.) | {   | Rupture of heart with diseased arteries. |
| b.) |   | Purpura.                                 |
| c.) |   | Pericarditis.                            |
| d.) |   | Ordinary form.                           |
| e.  | Uterine muscular fibres a week or two after delivery. |  |
| f.  | Granule-cells.  |  |
| g.  | Cancer-cells.   |  |

Pus-globules, epithelial cells, connective-tissue corpuscles, are all apt, in the course of inflammatory processes, to become granule-cells. Cartilage-

cells undergo similar changes; and the stellate corpuscles of the cornea, and those of the innermost coat of arteries, are equally liable to be the seat of fatty deposition. Fatty degeneration of muscular tissue is of much interest. It occurs as a normal process in the involution of the muscular walls of the uterus after parturition; it may often be detected in the hypertrophied muscular fibres of the walls of the stomach and intestines, when carcinoma or other such growths affect these organs; and it is occasionally present in the voluntary muscles. But it is chiefly met with in the muscular fibres of the heart, and has indeed been principally studied in connection with this organ. It commences here with the appearance of fatty granules in relation with the corpuscles which stud the substance of the fibres, and in the immediate vicinity of their poles; but gradually they get more general in their distribution, the fibres progressively losing their characteristic markings, and after a while becoming, like granule-cells, mere accumulations of granular matter. Fatty degeneration is often remarkably well seen in the cells of carcinoma, and many other kinds of morbid growths.

The term *caseation* is applied to that condition in which tubercles, syphilitic growths, carcinoma, and collections of pus, acquire the appearance and consistence of some forms of cheese. It is essentially fatty degeneration; but it is fatty degeneration in which there is a deficiency of moisture, in which the degenerate cells shrivel up instead of expanding and undergoing solution, and in which the diseased mass becomes dry and friable instead of pulpy or fluid. It was formerly supposed to be distinctive of tubercle.

*e. Pigmentary Degeneration.*—The deposition of pigmentary matter is not, any more than that of oil, necessarily a pathological process; nor, even when pathological, is it to be regarded as necessarily an evidence of degeneration. All pigment, originating within the body, appears to be derived from the hæmoglobin or red-colouring matter of the blood, or from the colouring matter of the bile, which is itself a derivative of hæmoglobin. In either case it may be simply diffused in a fluid condition among the tissues, or it may be deposited in the form of granules or small solid masses, or it may assume a crystalline shape. And in either case, again, it may present various modifications of colour; of which red, yellow, brown, and black may be taken as the types. The various stages of pigmentation may be observed superficially in the progress of a subcutaneous bruise; but to follow them thoroughly, it is necessary to investigate the changes which clots, and the tissues in which they are imbedded, present at different periods after extravasation. The blood-corpuscles soon lose their colouring matter, which speedily diffuses itself through the surrounding tissues, staining them, and more especially their protoplasmic particles, of a yellow colour. From this, ere long, granular pigment, of a yellow, brown, or black tint, is precipitated amongst the tissues, and in the clot itself; and, probably, at the same time, small refractive nodulated masses of a deep orange or pale red hue make their appearance. Lastly, small thick rhomboidal crystals, of a deep ruby colour, are produced

which are generally termed 'hæmatoidine' crystals. The final colour which the granular form of pigment assumes is either brown or black; and this together with hæmatoidine crystals, which are unalterable, is the permanent indication of the previous existence of extravasated blood. A nearly similar series of changes may be observed in the liver, in cases where the escape of bile is prevented:—namely, first, a general staining of the tissues, then a granular pigmentary deposit, and occasionally a more or less abundant formation of hæmatoidine crystals scarcely if at all different from those obtained from blood.

FIG. 30.—PIGMENTAL DEGENERATION WITH HÆMATOIDINE CRYSTALS.  $\times 250$ .

According to Städeler, bilirubine differs from hæmatoidine only in containing two more atoms of carbon; and the various modifications of colour which bile undergoes by keeping are due to the development of substances which differ from bilirubine only in possessing larger quantities of water, relatively to carbon and nitrogen.

The pathological precipitation of brown or black pigment in a granular form is well seen: in the cells of the rete mucosum in Addison's disease, and in the brown discoloration which often succeeds various forms of skin disease and cutaneous inflammations resulting from chemical or other irritant applications; in the cells of melanoid carcinoma and sarcoma; and perhaps in the cells of the testis and of the grey matter of the brain during the latter periods of life. The deposition of yellow, red, and brown pigmentary granules, and of hæmatoidine crystals, is, as before stated, a common result of the extravasation of blood; accordingly these matters are found in corpora lutea, in the neighbourhood of apoplectic effusions, and in the parietes, interior, and vicinity of small vessels obstructed by clots or otherwise diseased. In certain cases of malarial fever, in which the spleen is seriously affected, black pigment masses are formed in that organ through decomposition of blood-corpuscles, and are carried thence by the circulating blood and deposited in the capillary vessels of other parts of the system. Black deposit is frequently met with in the tissues of the lungs and bronchial glands, becoming more and more abundant as age advances. Here there is no doubt that the pigment is mainly, if not wholly, of extraneous origin; and is in fact the carbonaceous dust floating in the atmosphere, which, drawn into the lungs during respiration, is absorbed by the epithelial cells of the bronchial tubes, and just in the same way as pigments purposely introduced by tattooing, partly remains imbedded in the tissues and partly finds its way along the lymphatic vessels and into the lymphatic glands.

*f. Uratic degeneration.*—This occurs only in gout. It is characterised by the appearance of needle-like crystals of urate of soda in the substance

of articular cartilages, in the periosteum, synovial membranes, and tendons. They are observed mainly in connection with the protoplasm of the cells, are often irregular in their arrangement, but are apt to form opaque densely arranged star-like clusters.

FIG. 31.—CARTILAGE OF JOINT INFILTRATED WITH URATE OF SODA.  $\times 250$ .

appears dusted with minute granules, and then, as these multiply, becomes black and opaque to transmitted light. Later on, the enlarging granules run together, the blackness and opacity disappear, and the calcified tissue gets refractive and transparent. The cellular elements frequently remain

FIG. 32.—CALCAREOUS DEGENERATION OF CEREBRAL VESSELS.  $\times 250$ .

intact, or nearly so, during this process; and if they be stellate, and numerous, the result is the formation of a mass having a close resemblance to true bone. Calcareous granules have a superficial likeness to globules of oil, but may be distinguished from them by their ready solubility (with the giving off of bubbles of carbonic acid gas) in hydrochloric and other acids, and if they be round by displaying a cross when examined by polarised light. Rindfleisch supposes that the pathological deposition of calcareous matter, which in the blood is rendered soluble by the presence of carbonic acid, takes place primarily at the periphery of cell districts; and that it is due to the

*g. Calcareous Degeneration.*—This consists in the deposition of a combination of carbonate and phosphate of lime in some previously existing albuminoid matrix, with which it combines to form minute granules and spherules. These increase in size by concentric additions to their surface, and presently coalesce into botryoidal masses, the general form and arrangement of which are determined by the peculiarities of the tissue in which the process is going on. The precipitation of calcareous matter takes place almost exclusively in the intercellular substance, which first

appears dusted with minute granules, and then, as these multiply, becomes black and opaque to transmitted light. Later on, the enlarging granules run together, the blackness and opacity disappear, and the calcified tissue gets refractive and transparent. The cellular elements frequently remain intact, or nearly so, during this process; and if they be stellate, and numerous, the result is the formation of a mass having a close resemblance to true bone. Calcareous granules have a superficial likeness to globules of oil, but may be distinguished from them by their ready solubility (with the giving off of bubbles of carbonic acid gas) in hydrochloric and other acids, and if they be round by displaying a cross when examined by polarised light.

difficulty of reabsorption of nutrient matters which have found their way thither. This difficulty favours the separation of their more diffusible from their less diffusible constituents, and thus the removal of the dissolved carbonic acid, and the precipitation of the calcareous matters which the carbonic acid had rendered soluble. This explanation accords very well with Rainey's views on the formation of shells and bone.

Calcareous precipitation is very common. It occurs in the internal coat of arteries, and in the whole thickness of the walls of minute vessels, in tendon and cartilage, and even in the substance of skin. It is especially apt to take place in inflammatory and other adventitious products. Thus, we find plates of calcareous matter (often assuming the characters of bone) in old false membranes of the pleuræ and pericardium, in the lining of cysts, and in the choroid coat of the eye. And, indeed, most degenerative products (such as cheesy tubercles, inspissated pus and old clots), when they have lost their moisture, and their more soluble or diffusible constituents, become its seat, and, assuming a mortary condition, finally shrink into calcareous lumps. But, although earthy matter is deposited mainly in the tissues between cells, it is occasionally found in the interior of cells, and especially those of unstriated muscle. It is thus that the smaller arteries are sometimes converted into rigid cylinders, and large portions of uterine muscular tumours into calcareous masses.

## 2. *Necrosis, or Gangrene*

Several of the degenerations just considered, end, as we have pointed out, in the disintegration and death of the tissues which they affect. We do not intend to pursue this question further, or to speak of that form of death which results from the direct action of destructive agents; but we purpose discussing very briefly the subject of necrosis, or mortification. This often arises in the course of inflammation, and often affects rapidly developing morbid growths; but whether occurring in these cases, or under other morbid conditions, it is always due immediately to obstruction of afferent vessels, or to weakness of the heart's action, and the consequent more or less complete arrest of the supply of nourishment to the affected region.

When the death of any part of the organism takes place, the conservative influence of vitality ceases in it, its constituents fall under the unrestrained operation of chemical and other physical powers, and then undergo a series of destructive and often putrefactive changes, in virtue of which its complex organic constituents gradually get reduced to substances of much more simple elementary composition, and its various morphological elements lose, in a greater or less degree, their characteristic features. The rapidity, however, with which these processes take place, necessarily depends upon the degree in which conditions favouring them happen to be present. These are chiefly heat, moisture, and exposure to oxygen or air, and to the various microscopic organisms which air and water contain. Hence it follows that gangrene is especially rapid,

and its products especially fetid, when it occurs in superficial parts, or in the lungs, or in the course of the alimentary canal, where there is free exposure to oxygen in a more or less diluted form ; or when it occurs in parts which are juicy and loaded with blood, as they are if they have been the seat of inflammation, or if there has been previous obstruction of veins, or if the arteries have continued for a time to pump blood into them—when in fact the gangrene is what is usually called ‘moist.’ When there is little moisture of tissue, and that moisture admits of ready removal by evaporation, or in other ways, and especially if there be at the same time entire protection from the influence of atmospheric air, the changes which ensue are very slow ; the parts get inspissated, dried up, mummified ; and even delicate structures retain for a length of time their chemical and microscopical characters, in a very slightly modified condition. A good example is afforded by the changes which ensue in an extra-uterine fœtus long retained.

Bone, teeth, hair, horny matter, elastic fibres, and cartilage resist putrefactive processes in a remarkable degree. But all the softer albuminous or albuminoid tissues, and fat, rapidly change into a series of transitional compounds, the nature of which is very imperfectly known. Some, however (such as leucine, tyrosine, margarine, pigment, cholesterine, and triple phosphate), are fixed ; some are soluble but not volatile ; and others again are volatile and offensive, and give to gangrenous parts their characteristic fœtor. Amongst the last must be included sulphuretted hydrogen, sulphide of ammonium, and valerianic and butyric acids. Ultimately, most albuminous and fatty matters are reduced in large proportion into carbonic acid, ammonia, and water.

The visible changes which attend gangrene are not less remarkable than the chemical, but they closely correspond with those which characterise ordinary degeneration. The blood stagnates, and soon the colouring matter escapes from the red corpuscles, permeates the vessels, and infiltrates and stains all the tissues around. Thus, the course of the superficial veins gets indicated by broad livid lines. Soon the diffused pigment is deposited in the form of brown and black grains and even of hæmatoidine crystals, and its presence tends to give a characteristic hue to the parts. The red corpuscles themselves either melt away, or are converted into small angular pigmented bodies. The white corpuscles of the blood and other protoplasmic masses get opaque and granular, then the seat of deposition of molecules of proteinous matter and of oil, and finally after becoming caseous break up into fragments. The contents of fat cells ooze through their membranous parietes, and diffuse themselves in globules of various sizes among all the tissues ; and after a while the solid fats crystallise out, and plates of cholesterine make their appearance. Muscular tissue, whether striped or unstriped, suffers much the same changes as protoplasm ; it first becomes opaque and granular, soon presents oil and pigment-granules in its substance, and presently breaks up (the striped fibres often splitting into transverse discs) and forms a viscid confused mass. Double-contoured nerves early present obvious changes :

the axis cylinder undergoes the same transformations as other forms of protoplasm ; but the medullary sheath breaks up into globular, oval, and irregularly rounded refractive masses of an oily character, and presenting the peculiar features of what is termed by Virchow 'myeline.' Ordinary connective tissue swells up, becomes opaque and granular, and then melts away. And bone, although it retains its characteristic form and aspect, loses its animal matrix.

Many lowly organisms make their appearance in putrefying tissues, but by far the most important of these are the minute omnipresent bodies known as 'bacteria.' Indeed the evidence now seems to be conclusive that actual putrefaction is determined by the growth and multiplication of these bodies, and that the recognised effects of air and moisture in promoting the decomposition of dead and dying tissues are in reality due to the bacteria suspended in them.

We have adverted to the fact that the appearances and progress of gangrene vary according to the degree in which the dead parts are exposed to the conditions which promote putrefaction. But the nature of the organ involved also necessarily influences the nature of the result. Hence, we need not be surprised that gangrenous parts present great varieties of character. In internal organs, as the brain, the dead portion becomes soft and pulpy, and its colour opaque and yellowish, with perhaps a faint greenish tinge and a little red-mottling, and the cellular constituents get granular and fatty, and presently reduced to a mere detritus ; but no putrefaction ensues, no offensive matters are developed, and the more soluble and diffusible products are at once removed by absorption. When an inflamed or congested leg, or a strangulated bit of bowel, becomes gangrenous, the affected part contains an extraordinarily large quantity of blood which escapes into the tissues, and, assuming there the characters of black pigment, blackens them ; putrefaction takes place rapidly ; a sanious fluid, charged with decomposing elements, and containing numerous globules of oil and much pigment, pervades the tissues and perhaps forms blebs at the surface ; and bubbles of offensive gas probably appear in similar situations. When gangrene occurs in the lung, the tissue often looks anæmic (sometimes, however, it is black with congestion), and presents in the first instance a translucent greenish tinge, but soon breaks down into a turbid greenish pulp of horrible fœtor. In other cases again, as for example in sloughing ulcers, or carcinomatous growths, the parts which are actually dead assume a dirty opaque white or greyish appearance, and are thrown off in masses. Lastly, when the affected parts have been supplied with little blood, or rapidly lose the fluid which is in them by evaporation, the condition termed 'dry gangrene' results. They then shrivel up, and gradually, by the retention of the blood-pigment within them, acquire a deep maroon or black colour ; and, as was before pointed out, their decomposition proceeds very slowly, and they become dry and mummified.

## C. MECHANICAL AND FUNCTIONAL DERANGEMENTS

THE various morbid processes of proliferation and degeneration which have been described bring with them a host of *mechanical* and *functional* disturbances, which form essential elements of disease, and are often far more important, at all events far more striking, elements than are those other lesions which give rise to them. As regards functional disturbances, indeed, it is obvious that their presence implies the coexistence of some nutritive or other material lesion of the part or organ whose functions are disturbed; and that their gravity must depend far less on the amount or quality of this material lesion than on the importance of the affected organ in relation to the well-being of our higher faculties, or to the maintenance of life. Thus, a fibroma, connected with superficial parts, may attain enormous dimensions without materially influencing the general health; whereas a very small growth of the same kind, involving the urethra or intestine, would probably soon cause mechanical obstruction, and induce the usual symptoms of strictured urethra or bowel. And thus, again, a tubercular mass or an hydatid may exist for some time imbedded in the substance of the brain, and yet give very little sign of its presence there; whereas those functional disturbances of the central nervous organ, which we know as acute mania and epilepsy, depend on such slight lesions that they even now, in great measure, elude detection.

1. *Mechanical Derangements*

These consist mainly of (a) *displacement* of organs, (b) *compression*, *contraction*, and *impaction*, (c) *dilatation*, and (d) *rupture* and *extravasation*.

a. *Displacement of parts* is exemplified in the altered position which the heart assumes when it is subjected to the pressure of unilateral empyema, or of a mediastinal tumour, and which this organ, together with the lungs, acquires when there is extreme angular or lateral curvature of the dorsal spine; it is shown also in hernia, intussusception, and prolapse of the rectum, and in the various flexions and other displacements of the uterus.

b. *Compression, contraction, and impaction*.—These conditions scarcely need explanation, yet it may be well to illustrate them by their effects on tubular organs. Compression of a tube means that it is reduced in calibre, and perhaps modified in shape, by forces acting upon it from without; contraction signifies that its bore is diminished by the inherent action of its own walls, or by morbid changes taking place in them—that there is in fact a ‘stricture;’ impaction implies that its channel is occupied by some concretion or other foreign body. It is obvious that any of these conditions may end in the complete obstruction, or closure, of the tube.

The effects of *compression* are manifested when a large quantity of

blood or serum is effused upon the surface, or into the ventricles, of the brain ; when the lung shrinks under the pressure of accumulated pleural secretion ; when the heart gets flattened, and incapable of dilating, under the influence of blood which has escaped into the pericardium from a ruptured aorta ; when the trachea is squeezed by a goitre or aneurysm ; when the intestines are strangulated by bands, or the mouth of a hernial sac ; when the rectum is flattened by the pressure of a diseased uterus. They are shown also in many cases in which organs are the seats of interstitial growths :—in cirrhosis of the liver, the new-formed fibrous tissue contracts upon the essential elements of the organ amongst which it is distributed, and leads to their more or less complete destruction ; and the same thing happens, as regards the nervous centres, in the morbid condition now commonly termed ‘sclerosis.’

*Contraction* may be due, either to spasmodic action of the part affected, or to some growth (inflammatory or other) involving it. As examples of the first condition we have temporary contractions of the cerebral vessels, inciting epileptiform convulsions ; of the muscular walls of the bronchial tubes, causing asthma ; and of the sphincter ani and compressor urethræ, producing spasmodic stricture respectively of the bowel and of the urethra. As examples of contraction due to inflammatory or other such changes we may enumerate, obstructive disease affecting the several cardiac orifices ; laryngeal œdema ; malignant or other organic strictures of the œsophagus, the pyloric or cardiac orifice of the stomach, the ileo-cæcal opening, or the anus ; and similar affections of any part of the genito-urinary apparatus. Smaller and even microscopic tubes and ducts, such as those of the breast, kidney, and sebaceous glands, may of course become similarly obstructed.

*Impaction.*—There are few tubular organs in which impediment from this cause does not occasionally take place. In the vascular system, especially in the systemic veins, thrombi or clots not unfrequently form, and cause obstruction. And in the same system portions of such clots, or of inflammatory vegetations developed upon the cardiac valves, often get detached, and then carried onwards by the circulating fluid, until they reach some vessel too small to admit of their further progress, where consequently they get fixed, or impacted, and block it up. In the alimentary canal, and ducts which open upon its surface, concretions frequently form, and, becoming lodged, cause more or less serious consequences :—thus, the ducts of the salivary glands may be obstructed by salivary calculi, the common hepatic duct by gall-stones, and the intestine also by gall-stones of large size, or by indurated fæces. In the intestinal canal, moreover, indigestible substances, purposely or accidentally introduced, such as masses of hair, or vegetable fibres, and the like, occasionally form concretions. Calculi again are of common occurrence in the urinary cavities and passages. In considering this subject we must not forget to advert to the impaction, or (what is equivalent to impaction) the accumulation, of abundant or tenacious secretions in cavities or canals, by which they are apt to become choked ; as occurs in bronchitis, when the bronchial

tubes are overloaded with muco-purulent fluid, and in inflammation of the kidneys, or in Bright's disease, when the renal tubules get blocked up by epithelial masses, blood, or fibrinous casts.

*c. Dilatation* of cavities depends, for the most part, on some disproportion between the pressure which their contents exercise upon their parietes, and the force which these parietes are capable of exerting in opposition to that pressure; and hence may be caused, either by unwonted accumulation of contents, or by undue weakness of parietes, or by the concurrence of these two conditions. It should be added that even when dilatation does not originate in morbid weakness (however produced) of the walls of a cavity, it very soon causes it. But dilatation may occur in cavities of new formation, as well as in such as are of normal presence, and hence its discussion involves that of the growth, if not that of the origin, of cysts.

*Cysts* are commonly classified as a subdivision of tumours. A little consideration, however, will suffice to show that they differ essentially from true tumours (that is to say, from neoplastic or proliferating growths), in the facts, that they are not themselves neoplasms; and that when they occur, as they often do, in association with such growths, that association is a mere accident, depending either upon some structural peculiarity or upon some special tendency, of the part affected, or of the neoplasm itself. Cysts may be divided generally, in accordance with their mode of development, into at least four different groups, namely: (i.) those formed by dilatation of natural cavities; (ii.) those resulting from distension of ducts; (iii.) those caused by extravasation of blood; and (iv.) those originating in the softening and destruction of tissue, or in the dilatation of natural alveolar spaces. In one or other of the first two classes must be included cysts, arising in various parts of the body, from dilatation of cavities or channels in connection with foetal structures, whether during foetal life itself, or, owing to the occasional persistence of such structures, at any time subsequent to birth.

i. *Cysts by distension of natural cavities.*—Among these must be included the pleuræ, pericardium, peritoneum, tunicæ vaginales, and synovial cavities, distended with dropsical or inflammatory exudation. They are exemplified also in the dilatations of the ventricles of the brain and cord, which constitute respectively the morbid conditions known as 'hydrocephalus' and 'hydrorrhachis,' and in the malformations of the same organs, termed 'encephalocele' and 'spina bifida.' Dilatations of the cavities of the heart, aneurysmal tumours of arteries, varicose conditions of veins, ovarian cysts, and cysts of the broad ligament, thyroid body, and many other organs, fall more or less obviously into this group.

ii. *Cysts by distension of ducts, or 'by retention,'* are even more common and more important than the last. We meet with them in the lungs, when the bronchial tubes are dilated, or when emphysema is present. They occur in all parts of the alimentary canal:—in the œsophagus, when its walls are paralysed, or there is obstruction at the cardiac orifice; in the stomach itself under analogous conditions; and in

any part of the large or small intestines above the seat of an impediment, or when the parietes are weakened by inflammatory changes. When the hepatic, pancreatic, or salivary ducts are obstructed by concretions, the tubes behind dilate. Cysts from this cause are exceedingly common throughout the whole of the genito-urinary apparatus: as, for example, when the bladder is distended, secondarily to the presence of a urethral stricture; when, under similar circumstances, the ureters and cavities of the kidneys dilate; and when, owing to their obstruction, the tubules of the kidneys expand into renal cysts. They occur also in the uterus and Fallopian tubes, and in the tubules of the testes, in consequence of stricture or other impediment to the escape of their contents; and so again in the breast, and in the sebaceous and almost all other glands.

A variety of this mode of formation of cysts has been observed, by Dr. Wilson Fox and others, in certain cases of multilocular cystic tumours of the ovary. They state that papillary growths take place from the inner surface of a comparatively large cyst; that these, as they increase in length and bulk, get closely wedged together; and that at length they coalesce in numerous points, leaving irregular chinks between them—which chinks, by the retention of the secretions of their parietes, gradually dilate, and ultimately form distinct cavities.

iii. *Cysts by extravasation*.—Blood effused either into cavities, or into the substance of organs, undergoes a series of degenerative changes. In some instances these result in the softening and breaking down of the central portion of the clot, and the consequent formation of a cyst. The best examples of such cysts are furnished by the brain and the cavities of the heart—in the former case as a result of the changes which take place in apoplectic effusions; in the latter, as a consequence of the softening of coagula which have formed some time anterior to death. Clots imbedded in the substance of the brain almost always undergo absorption, and leave behind them cysts filled with clear fluid, traversed by delicate filamentous bands, and bounded by tissue still coloured with blood-pigment; those occupying the cavities of the heart break down into an opaque milky fluid, charged with degenerate blood-elements. It not unfrequently happens that cysts are formed in the interior of sarcomatous and other soft and highly vascular tumours, by exactly the same process as that which produces apoplectic cysts. It may be added that extravasated blood, especially if it be extravasated in successive strata, in many cases forms solid masses, which may become organised, and which constitute, according to their position, the various forms of ‘blood tumour’ or *hæmatoma*.

iv. *Cysts by softening of tissues*.—These are generally due to the occurrence of one or other of the degenerative processes which have been described. We meet with them in abscesses, and in cases where tissues have undergone mucous, colloid, or fatty softening. Hence, putting abscesses on one side, they occur most frequently in proliferating growths; and, indeed, in some cases of disseminated malignant tumours the tendency to become thus hollowed into cavities is general. Bursæ in unwonted situations must be included in this group.

It may be worth while to point out that, as cysts dilate under the influence of their accumulating contents, their parietes, which often increase at the same time in thickness, tend to tear or yield at points in their outer surface; that thus pits which gradually increase in area and in depth are formed; and that these not unfrequently end in perforation or rupture, and, in the case of cysts separated by a party-wall, in the establishment of communications between them. We should also mention that the inner surface of cysts, contained within the substance of proliferating growths, may, however the cysts have been produced, get lined with epithelium, and the seat of new outgrowths; and that hence we not unfrequently see fungous, papular, villous, or cystic formations springing from the inner surface of such cysts, just as they may spring from the diseased mucous, serous, or cutaneous surface.

*d. Rupture and Extravasation.*—The occurrence of rupture and extravasation, to which the distension of cavities and canals ultimately tends, is an event of great pathological importance, and often of the gravest danger. Such accidents are common. Sometimes the heart is torn, and the pericardium consequently gets distended with extravasated blood. The rupture of aneurysms and of varicose veins is of frequent occurrence. In the lungs, the progress of vesicular emphysema is largely dependent on rupture of air-cells; and in interlobular emphysema, and pneumothorax, we have not only laceration of tissue but extravasation of air. Laceration of the stomach in ulcer of that organ, or of the intestine in the course of typhoid fever, is attended with the escape of its contents into the peritoneal cavity. Again, abscesses and hydatid cysts often rupture, and discharge their contents; and, indeed (as we have already pointed out), cysts of all kinds are liable, in various degrees, and with various results, to similar accidents.

## 2. *Functional Derangements*

To discuss these thoroughly would involve an analysis of nearly all the symptoms of all diseases. Morbid processes, indeed, are mainly recognised during life by the functional disturbances to which they give rise; and some diseases (so far, at least, as we know them) are nothing more than groups of such disturbances. Every organ of the body, every particle of the organism, has its proper duties to discharge; and, under the influence of morbid processes, these duties become increased or diminished, and in either case probably more or less profoundly modified. The function of the eye is to see, that of muscle to contract, that of the kidney to excrete urine; but the eye may be unduly sensitive to light, or its power of distinguishing objects may be impaired, or it may see things which have no real existence; muscle may contract with spasmodic violence, or it may be thrown into convulsive movements, or it may lose its power of action altogether; the kidney may cease to excrete urine, or it may separate from the blood a portion only of the usual urinary solids, or it may discharge matters which are altogether foreign to the normal constitution of that fluid. In these and many other ways, the organs

which have been named may present signs of functional disturbance ; and it is clear that similar observations may be made in reference to every other organ. We do not purpose, however, to enter here upon the consideration of functional derangements generally, for most of them will best be discussed when we come to speak of local diseases. But some, which are connected more especially with the vascular and nervous systems, enter so largely into the complex phenomena of disease, and form such important elements in diseases which are fundamentally distinct from one another, that it will be convenient to discuss them separately, and at once. We refer mainly to *congestion*, *dropsy*, *fever*, *the typhoid condition*, *collapse*, and *death*.

### a.—*Congestion*

Accumulation of blood in the vessels of a part is necessarily associated with dilatation of these vessels ; but, as we have pointed out in speaking of inflammation, this dilatation may be active, and the accumulation of blood therefore secondary to it, or it may be passive, the vascular walls yielding under the pressure of the blood within them.

i. *Active congestion* is due to active dilatation of vessels, or, at any rate to that kind of dilatation which may be evoked by direct stimulation of the dilator nerves of the vessels or by reflex irritation. This dilatation commences for the most part in the small arteries, and presently involves the capillaries and small veins. Active congestion is possibly connected with inflammation, at least in its earlier stages, and generally attends morbid proliferation. And as, in health, we recognise its temporary presence in the cheek which blushes with shame, and in the general surface after violent exercise, so, in disease, we recognise its temporary presence in the hectic flush of phthisis, and in the general redness which attends many forms of febrile disturbance.

ii. *Passive congestion* has been divided, unnecessarily as it seems to us, into two varieties, namely :—first, that which is dependent solely on loss of power in the walls of the dilated vessels ; and, second, that in which the dilatation is traceable to some mechanical impediment to the passage of blood through the veins. There is doubtless a theoretical distinction between them ; yet it is obvious that in both cases the dilatation is really passive, and due to the fact that the vessels yield under the internal pressure to which they are subjected. The first case is exemplified by that dilatation of vessels which attends the later stages of inflammation, and by that permanent enlargement of them which is often seen in the vicinity of old ulcers, and of inflammatory and other formations, and is so common in the noses and cheeks of persons who are given to drink, or have been exposed to the influence of weather, or suffer from acne rosacea. The second variety is observed generally in obstructive heart-disease, and under analogous circumstances in limited districts of the body. In disease of the mitral valve, in emphysema and some other affections of the lungs, and especially in disease of the valves

of the right side of the heart, the blood gets delayed in the systemic veins: the trunk-veins, their tributary branches, and their capillary veins successively undergoing dilatation. We often see, in such cases, groups of minute subcutaneous veins forming varicose tufts, persistent livid congestion of the nose and cheeks, hands and fingers, feet and toes, due to general over-distension of their capillary veins and capillaries, and, more important than all, congestions of internal organs—especially of the liver, which assumes the ‘nutmeg’ condition, and of the kidneys, which get indurated and excrete albuminous urine. Again, whenever a vein is obstructed by a thrombus, or external pressure, the tributary veins undergo precisely the same changes which the veins undergo generally in heart-disease. Thus, if there be an aneurysm, or other tumour in the upper part of the chest, and the descending cava or one of its branches be compressed by it, the veins of the head and neck and upper extremities, or those of one side of this portion of the body, get distended; if the femoral vein be blocked up by a clot, the veins of the foot and leg suffer similarly; if the lateral sinus be obstructed, enlargement and congestion of the retinal veins, and of the veins of the conjunctivæ and eyelids, not unfrequently occur. So also when, owing to cirrhosis or other hepatic disease, the passage of blood through the portal vessels is impeded, the veins of the mucous membrane of the stomach and bowels become over-distended and occasionally relieve themselves by actual hæmorrhage. It should not be forgotten that the mere statical pressure of a column of blood, which is competent to produce a varicose condition of the larger veins of the lower extremities, is competent also to produce dilatation of the smaller veins and capillaries; and further, that mere feebleness of the heart’s action—in other words, incompetence to propel the blood efficiently, as occurs in the later periods of heart-disease—leads to stagnation of blood in the capillary and other small vessels, and hence to passive congestion; and that, on almost the same principle, obstruction of an artery, as in the lung and kidney, very often allows the territory to which it is distributed to become the seat of intense congestion and even of hæmorrhage.

### *b.—Dropsy*

Dropsy is the accumulation of serous fluid within the cavities of the body, or in the areolar spaces of the connective tissue. It depends either, like passive congestion, upon mechanical obstruction to the flow of blood along the veins, or upon the presence of inflammatory or other analogous processes, or upon some morbid condition of the blood or blood-vessels, or, lastly, upon obstructive diseases of the lymphatic tubes or glands. Further, dropsy may be local or general, and dependent therefore on local circumstances or on causes which act universally. There is reason to believe that a morbid state of the walls of the capillary vessels is an essential factor in the causation of dropsy.

i. The causes of *general dropsy*, or *anasarca*, are for the most part obstructive diseases of the heart, morbid conditions of the lungs impeding

the circulation through the pulmonary vessels, affections involving the secreting structure of the kidneys, and certain morbid states of the blood or tissues. The general dropsy which attends heart or lung disease is, like the congestion which also attends these affections, purely mechanical, and indeed may be regarded as the sequel of that congestion. In the healthy condition the thin walls of the capillary vessels and small veins allow a constant escape of the serum of the blood into the tissues external to them—the quantity, which thus escapes in a given time, being largely dependent on the varying degrees of pressure within the vessels, and on the more or less facility with which the lymphatic vessels perform their proper absorbent function. Now when a mechanical obstacle exists to the transit of blood through the heart or lungs, the systemic veins and capillaries soon get overloaded, and the pressure upon their inner surface rapidly increases. And we can readily see that, while there arises, on the one hand, an increased tendency for the serum of the blood to transude at the peripheral distribution of the venous system, there is developed, on the other hand, a tendency at the opposite end of the system to impede the entrance of the contents of the thoracic duct; and that hence the fluid, which is effused into the tissues in abnormal quantity, is absorbed with difficulty, and dropsical accumulation necessarily ensues. It should be observed that the effusion is not simply, although it is mainly, fluid, but that it always comprises a considerable proportion of leucocytes, and generally some red corpuscles. Cardiac and pulmonary dropsies are, as their mechanism would indicate, always associated with congestion, and almost invariably first show themselves in the most dependent parts. The explanation of renal dropsy is not so clear. It obviously does not depend on any obstacle to the circulation existing in the heart or lungs, or on over-distension of the venous system with blood, or on any similar distension of the capillary vessels; for the patient usually presents an anæmic appearance, even when the blood itself is not abnormally pale. There is, however, in renal disease very unmistakable obstruction throughout the whole capillary arterial system; for, as Dr. George Johnson has well shown, the small arteries generally become extremely thickened and their canals proportionately contracted; and we know that the left ventricle of the heart hypertrophies to overcome some impediment (doubtless the mechanical impediment which Dr. Johnson has discovered existing at the periphery of the vascular system), and that, associated with these conditions, there is, as we should expect, greatly increased blood-pressure in the arteries. It seems hardly likely, therefore, that in this case the escape of fluid into the tissues should take place from the capillaries and capillary veins; but, on the other hand, it seems very probable that it occurs through the thickened capillary arteries, in consequence of the extreme internal pressure of fluid to which they are subjected. It can scarcely be objected to this explanation, that the thickened walls of the small arteries, would materially counteract the tendency for fluids to transude through them, in face of the fact that the hyaline thickening of the walls of the Malpighian vessels of the kidney, in lardaceous disease of that organ, is not incompatible with

a profuse discharge of urine. In pure renal anasarca the skin is usually remarkably anæmic and waxy-looking, and the dropsy is often first detected, not in the lower extremities, but in the eyelids and scrotum. General dropsy occasionally takes place in persons who, from whatever cause, are in a state of anæmia; it is especially common in chlorotic girls. We know that in these cases the blood is in a state of unnatural dilution; that the muscular tissue generally, including that of the heart and probably that of the blood-vessels, is enfeebled; and that the circulation, therefore, even though the heart acts quickly, is languid; and we are hence justified in assuming that the anasarca is due either to the fluidity of the blood, or to the languor of the circulation, or to a combination of these conditions. The supervention of anæmia, in the course of disease of the heart or kidneys, is very often the determining cause of an attack of anasarca which otherwise would have been escaped; and hence anæmia is, in many respects, a very serious complication of the diseases of these as well as of other organs.

ii. *Local dropsy* depends either on mechanical obstruction of the principal vein or veins leading from the dropsical part, or on obstruction of the lymphatics, or on the presence of inflammatory or other like processes. When it depends on venous obstruction, we have, within a circumscribed space, very nearly the same conditions as those which, in cardiac disease, affect the whole body: a vein is impervious; its tributary branches down to the capillaries get distended with blood, the serum of which presently escapes into the tissues in larger quantities than the lymphatics are able readily to remove. The most important variety of local dropsy from venous impediment is that which takes place in the abdomen when the passage of blood through the portal vein is impeded: as in cirrhosis, or by growths occupying the transverse fissure of the liver. But any vein may be obstructed either by pressure from without or by a coagulum within it. Thus, by obstruction of the superior cava, enormous anasarca, limited to the head and neck and arms, may be produced; from obstruction of the inferior cava (even from so slight an amount of it as results from the pressure of ascitic fluid), dropsy limited to the lower extremities may arise; and, in consequence of obliteration of the brachial or femoral vein, anasarca of the corresponding arm or leg may ensue. It has already been pointed out that, whenever inflammation is in progress, a considerable excess of the serum of the blood is poured out into the tissues; and that, especially when the parts involved are lax or present some suitable structural peculiarity, the effused serum accumulates in them, producing a more or less obvious dropsical condition. We see this in the œdema of the eyelids, which attends the formation of a common styé; in the dropsical condition of the tissues around the joints, in rheumatism and gout; in the œdematous state of the leg, when erythema nodosum or slight periosteal inflammation is present; but we see it especially in inflammation of the serous and synovial membranes—inflammation of the pleura causing hydrothorax, inflammation of the pericardium hydro-pericardium, inflammation of the peritoneum inflammatory ascites, and

inflammation of the synovial membrane hydrops articuli. Effusion of serum in excess also attends the development of tubercle, and of carcinoma and other forms of malignant growths; and consequently we often find the serous cavities full of dropsical fluid, in connection with the growth of such tumours from their parietes. It may, perhaps, be a question, in some of these cases, as to how far the dropsy is due to the mere excessive effusion naturally attending morbid proliferation, how far it may be attributed to obliteration of some of the veins leading from the great omentum and other parts. The last form of dropsy to which we have adverted is that due to lymphatic obstruction. We have already briefly considered this subject in connection with fibroma and lymphoma; and need say no more about it now, than that the lymphatics of a limb or organ occasionally get obstructed, and that then (to take the case of the limb) the whole member becomes tense, elastic, pale, and infiltrated with fluid, having the chemical and microscopical characters of lymph; that the tissues thus soaked in nutrient fluid tend to become hypertrophied; and that here and there subcutaneous vesicles, which may be regarded as simply dilated lymphatic passages, make their appearance, and from time to time rupture, and discharge lymph.

In cases of general dropsy, whether of cardiac or renal origin, both the general connective tissue and the various serous cavities, as a rule, suffer in pretty nearly equal proportion; but now and then, in association with slight anasarca, there may be extreme ascites, or extreme effusion into one of the pleuræ. In such cases the local excess is necessarily due to the co-operation of some local cause—the ascites, for example, to a nutmeg condition of the liver, or to slight peritoneal inflammation; the pleuritic accumulation either to slight general pleurisy, or to the circumscribed serous inflammation which is usually excited in the neighbourhood of pulmonary apoplectic clots.

#### *c.—Fever*

By the term 'fever' is meant that abstract condition which is common to all so-called 'febrile disorders,' and the presence of which gives them their claim to that designation. Essentially it means, undue elevation of temperature; the immediate or approximate cause of that elevation; and the consequences which these conditions entail.

i. The *normal temperature* of the body has been variously estimated, but, on the average, seems, in the adult, to range between  $98.4^{\circ}$  and  $99.5^{\circ}$ , in the infant to stand at a somewhat higher figure. It presents, however, within narrow limits, numerous variations. First: the most constant and important of these is the diurnal variation, which rarely exceeds  $1.5^{\circ}$ , but occasionally amounts to as much as  $3.5^{\circ}$ . The minimum temperature, according to Dr. Jürgensen, occurs from 1.30 A.M. to 7.30 A.M., the maximum from 4 P.M. to 9 P.M.; the temperature between 7.30 A.M. and 4 P.M. rising with some fluctuation, that between 9 P.M. and 1.30 A.M. gradually falling. This daily variation corresponds pretty accurately to similar variations in the activity of respiration and circulation. Second: a slight

but decided elevation of temperature usually follows the ingestion of food. Third : muscular exercise has a similar influence ; although, as Dr. Davy has shown, this elevation manifests itself, less by actual increase of the temperature of the internal organs, than by the general diffusion of temperature throughout the organism. Fourth : the external temperature, again, influences that of the body in a greater or less degree. But, under ordinary circumstances, its influence is much less than might be supposed ; for variations of season in our own climate have a scarcely perceptible effect, and even tropical heat and arctic cold rarely disturb the temperature of the internal organs beyond a degree or two. The influence of external temperature depends, however, upon the conditions under which it is exerted ; for, if these be favourable, the general heat of the body may be largely and rapidly augmented or lowered, and even to a degree which is incompatible with the maintenance of life. Thus, whenever the medium (air or water), in which the body is immersed, is in rapid movement, it will, if of a higher or lower temperature than the body, elevate or depress its temperature in a much greater degree than if it were at rest ; and again, whenever perspiration is impeded, as it necessarily is in a moist atmosphere, or in water, the effects of heat are exerted with special efficacy.

The conditions which determine the heat of the body, and which regulate it, have been investigated with considerable success. It is certain, in accordance with the laws of force, that no heat can be developed in the body save such as may be traced, directly or indirectly, to the latent heat of the substances which are ingested as food ; that the total amount of heat which the body is capable of evolving is simply that which would be emitted in the course of its entire destruction by burning ; and that, neither in its parts nor as a whole, has it any more power of creating heat than of creating matter. It is obvious, therefore, that the development of heat in the body is due simply to the setting free of latent heat by the destructive oxidation which is constantly going on in it ; and that the quantity of heat developed in any given time is an exact measure of the amount of oxidation which has taken place in that time. It is equally obvious, that the excreta furnished by the skin, lungs, kidneys, and alimentary canal (representing as they do the lowest degree of degradation to which, after various changes, the alimentary matters have become reduced), must furnish the means of determining exactly both the amount of oxidation which has been effected, and the amount of heat which has been evolved. Ranke, by comparing the daily quantity and quality of the food with the daily quantity and quality of the excreta, has arrived at the conclusion that the healthy adult body evolves on the average enough heat in twenty-four hours to raise 44 lbs. of water from the freezing to the boiling point ; and it has been estimated further, that of this heat 2·6 per cent. goes to the elevation of the temperature of the food ingested ; 5·2 per cent. to the warming of the air breathed ; 14·7 to the vaporisation of the water discharged by the lungs ; and 77·5 to the radiation and evaporation from the skin.

The above statements, however, only represent the final result which is attained, after many transmutations within the body, during which heat becomes alternately latent and sensible. We know, for example, that heat is as essential for the maintenance of the corporeal functions, as it is for that of the functions of the steam engine ; that every act of growth and development, every nervous operation, every muscular contraction, is dependent on the heat developed by oxidation, and is attended with the temporary disappearance or absorption of a certain quantity of heat ; while, on the other hand, everything which interferes with, or impedes, or arrests the performance of these functions (the friction of the blood against the walls of the capillary and other vessels, and of the muscular fibres against one another, every opposed muscular effort, and possibly even the constant passage of nervous currents along the nerves), is attended with the reappearance of that heat in a sensible form.

It remains to consider on what conditions the regulation of the amount of heat developed, and the regulation of the temperature of the body, depend.

As regards the former question, there can be no doubt that that degradation of tissue and of material which results in the evolution of heat, although in itself a purely chemical process, is indirectly largely under the influence of the nervous system, and especially of its sympathetic portion ; for it is to this that the varying rapidity and force of the heart's contractions, and the varying diameters of the vessels (which between them so powerfully affect the molecular changes which are going on in the body), are due ; and it is possibly by its direct operation on the essential elements of glandular organs that the secretions of these organs are to a large extent regulated.

The maintenance of the body at a uniform temperature is due to the existence of a remarkable power of adjustment between the amount of heat developed in the interior of the body, on the one hand, and the amount of cooling, on the other, which takes place during respiration by the admission of cold air and the exhalation of water, and at the cutaneous surface by radiation and evaporation—processes, however, which again are under the control of the nervous system. The equalisation of the temperature of the body is dependent on the circulation of the blood : the more active this is, the more does the temperature of the surface and extremities approximate to that of the internal organs, and at the same time the more rapidly is the general cooling of the body effected ; while, on the other hand, the more feeble the circulation, the cooler do the surface and extremities become, the wider grows the difference between the temperature of these parts and that of the interior of the body, and the more slowly does the internal temperature undergo reduction.

The nervous mechanism that regulates the temperature of the body, and influences the metabolic processes which are attended with the evolution or the absorption of heat, is believed to have its centre above the medulla oblongata, and not improbably in or near the pons varolii.

ii.<sup>1</sup> The presence of *abnormal* or *febrile temperature* is usually attended with various symptoms and phenomena more or less characteristic of the febrile state. The skin gets hot, the pulse and respirations accelerated, the gastro-intestinal functions impaired or modified, the urine and other secretions diminished, and headache and muscular pains are complained of. There is generally also a tendency for the febrile phenomena to assume a remittent character, for paroxysms to recur perhaps once or twice in twenty-four hours, and for each paroxysm to comprise three more or less distinctly marked periods, known respectively as the cold, the hot, and the sweating stage. In the first of these the patient feels chilly or cold, shivers or has rigors; in the next his skin gets hot and dry; and in the third perspirations break out.

The increase of temperature may vary from the slightest rise above the normal up to 110° or 112°. If it do not exceed 101°, slight febrile action only is present; if it lie between 101° and 103°, the febrile condition may be regarded as 'moderate'; if between 103° and 105°, the fever is considerable or 'high'; if it exceed 105°, the febrile disturbance is excessive, and there is usually considerable danger; from 106° upwards the temperature is frequently termed *hyperpyretic*; and (with one or two notable exceptions) if it surpass 107° or 108° death is almost certain to supervene. Febrile temperatures, like normal temperatures, undergo variations; and on the whole (excepting when interfered with by the influence of specific diseases) these correspond to the normal variations, but are exaggerations of them. Thus, there is usually a matutinal fall and an evening rise, and the difference between them generally amounts to 2 or 3 degrees; but it may be much more considerable.

The skin is usually dry and hot, but it is liable to considerable changes. Not unfrequently, during the early period of a febrile attack, or of a febrile paroxysm, while the internal parts of the organism are preternaturally hot, the vessels connected with the surface of the body, especially those of the limbs and head and face, are so contracted as to allow comparatively little blood to reach the surface. This then looks shrunken and dusky, and in certain parts, especially the hands, feet, nose, and ears, may even be much colder than natural. But more or less general heat of skin is present even when the surface displays this appearance of chilliness; and before long the contracted vessels dilate, blood is admitted freely to the comparatively exsanguine parts, which then become plump, congested, dry, and often to the touch pungently hot. This latter condition is usually succeeded after a time by more or less copious perspiration.

The frequency of the heart's beats is always increased, and this increase has usually some relation to the temperature present. Thus, if the latter range from 100° to 101°, the pulse usually ranges from 80 to 90; if the temperature range from 101° to 103°, the pulse ranges from 90 to 110; if the temperature range from 103° to 105°, the pulse ranges from 120 to 130. With still higher temperatures, the pulse may rise to

<sup>1</sup> Several corrections and additions to this article have been derived from Dr. Burdon Sanderson's papers on the 'Process of Fever' in the *Practitioner* for 1876.

140, 160, 180, or even over 200 beats in the minute. The rule, however, which is here laid down is liable to frequent exceptions: especially in the case of irritable or nervous persons, in whom the pulse, in relation to temperature, is usually disproportionately frequent. The character of the pulse varies. In its typical condition it is more or less large, hard, and bounding, and its trace displays a sudden rise with an almost equally sudden fall, but no indication of diastole. This is its state during the height of fever. But during the cold stage it is small and hard, and in the sweating stage large and soft.

Although increase in the frequency of the respirations is undoubtedly one of the normal phenomena of fever, and we often observe the respiratory acts rising to 30 or 40, and in the case of children to 50 or 60, in the minute, the respiration-rate does not bear that close relation to the temperature which the pulse-rate does. It is not uncommon to find the respirations normal in frequency even when the temperature is considerably elevated; and, on the other hand, to find them greatly accelerated in febrile states of the mildest type. When the temperature is hyperpyretic, the respirations are usually very rapid and shallow, and the inspirations often attended with opening of the mouth and of the alæ nasi, and with a sniffing, sipping, or sucking sound. The amount of air respired in fever in a given time is always considerably greater than in health, and although the expired air contains a diminished percentage of carbonic acid, the total quantity of carbonic acid discharged appears to be largely increased.

Thirst is usually present, and often extreme, and for the most part there is impairment or loss of appetite; the mouth feels dry and clammy, and acquires a bitter taste; and the tongue tends to be coated and dry. The bowels generally are constipated.

The urine is almost invariably modified in character: it is scanty, high-coloured, of high specific gravity, and deposits on cooling a more or less abundant sediment of urates and perhaps uric acid. But although the bulk of urine passed daily is generally below the healthy average, the quantity of solid matter which is passed with it is usually above the average. The chief increase here is in the urea, of which more than twice as much may be excreted as in health. Dr. Parkes has discovered 885 grains in the day's urine of a patient suffering from enteric fever, Alfred Vogel as much as 1235 grains in that of one suffering from pyæmia, and Dr. Austie over 1600 in that from a case of pleuro-pneumonia. Uric acid also is increased, and may be increased twofold. Again, the colouring matter may amount to three or four times the quantity discharged in health, and there is a rise in the quantities of hippuric, sulphuric, and phosphoric acids and of the salts of potash. On the other hand, chloride of sodium and other salts of soda are diminished. Febrile urine is usually more acid than healthy urine. But although the general fact of the increase of the solid constituents of the urine in fever has been well ascertained, it has also been well ascertained that the discharge of solid matters occasionally falls, sometimes suddenly, sometimes gradually, far

below the normal, the urine becoming pale, limpid, and of low specific gravity. Such occurrences, however, are only of temporary duration, and are always followed sooner or later by an abundant discharge of effete matters which had been accumulating in the system.

Among the febrile phenomena referrible to the nervous system may be enumerated, headache, vertigo, delirium, a sense of weariness, soreness or aching in the loins and limbs, and alternations of subjective chilliness with flushes of heat. The sensation of chilliness is exceedingly common, and occurs most frequently at the beginning of a febrile paroxysm. It is often associated with rigors. These are violent tremulous movements of all parts of the body (legs, arms, trunk, head, and neck), attended with chattering of the teeth and that pallor or duskiness of surface which has already been adverted to. The patient feels intensely cold, although the interior temperature of his body is probably far above the normal. Rigors appear to be explicable by the fact that, owing to excessive contraction of its arteries, the skin receives less than its due share of blood, and less than its due proportion of the heat generated within the body. It is, therefore, either generally or in certain parts, relatively cold. The feet, hands, nose, and ears, indeed, are often livid, shrunk, and actually cold. Rigors may not unfrequently be reinduced by exposing portions of the surface to the influence of the air. In children, convulsions sometimes take their place.

There are several points of interest in relation to fever which may be briefly referred to. First: it is a remarkable fact that, notwithstanding the extreme thirst of most fever patients, and the large quantities of fluid they drink, but little water comparatively is discharged from the kidneys or bowels, and often little apparently from the skin. Dr. Parkes suggests that this may be due to the presence in the system of some intermediate waste product which, like gelatine, is powerfully hygrometric. There is reason, however, to believe that the collective discharge of water is usually much greater than it seems to be, and than it is in health, and that in fact a considerable proportion of the loss of body-weight of fever-patients is due to this cause. If, then, the discharge of fluid from the bowels and kidneys be diminished, it is obvious that there must be augmented discharge from the lungs and skin. And, as regards the skin, it may be observed that it is only during the cold stage and during rigors that exhalation is in abeyance, that in the sweating stage the discharge of fluid is obviously excessive, and that even during the hot stage the escape of watery vapour by insensible perspiration is abundant. Second: the condition of the blood is a matter of much interest; yet little of importance is known about it. It seems, however, that after a time the red corpuscles, albumen, and alkaline salts diminish in quantity, and the blood consequently becomes impoverished. Third: that excessive waste of tissue goes on during fever is plainly shown by the condition of the urine, and by the gradual and often rapid emaciation of the patient, which occurs even if he be taking considerable quantities of nutriment. The tissues that especially suffer are the fat, which may almost entirely dis-

appear, and the muscles, which dwindle away in a remarkable degree. But the more permanent tissues, such as the bones, also undergo some diminution. Recent observations show that, although the amount of urinary solids discharged daily in fever is often not larger than that discharged in health, the amount is always much larger than that which would be discharged in health under fever diet. It has also been shown that the increase in the urea precedes the elevation of temperature, and that it is maintained even during defervescence. That this urea is due mainly to the disintegration of the tissues of the body and of the blood-cells, and not, as in health, mainly to the albuminous matters derived directly from the food, is proved by the fact that the salts of potash (which are normal constituents of the living tissues) become excessive in febrile urine, whereas the salts of soda (which abound in the plasma of the blood, and in food, and which in healthy urine exceed those of potash) diminish, sometimes almost to zero, to reappear in excess during convalescence, when the potash salts decrease. The undue disintegration of the red blood-cells is demonstrated by the excessive presence of colouring matter in the urine. Fourth: the supervention of convalescence is described as taking place in two different ways—gradually by *lysis*, or suddenly by *crisis*. In the former case all the febrile phenomena gradually disappear, and the patient lapses gently into convalescence. In the latter case the progress of the attack is abruptly arrested with the appearance of a so-called ‘critical’ discharge (copious perspiration, profuse diarrhoea, or abundant secretion of urine loaded with effete matters), by means of which it is supposed that the morbid blood rapidly purifies itself. But fifth: fever may also end in death. This event, however, can rarely be attributed to the influence of fever alone, inasmuch as fever is always secondary to some specific or other disease of which it is a mere epiphenomenon or symptom. Nevertheless it is obvious, if we consider the physiological and other recognised consequences of fever, that fever itself tends to the induction of death in some two or three different ways. The chief of these appear to be asthenia, blood-poisoning, and the direct influence of sustained high temperature. The continuous excessive waste of tissue, with the consequent emaciation, loss of strength, and impairment of the functions of various organs (which is an essential element of the febrile state), must clearly, if it be not arrested, involve sooner or later a fatal issue. The progress of the hectic fever of phthisis, and other chronic wasting disorders, furnishes a sufficiently apt illustration. This waste of tissue necessarily leads also to the passage through the blood of an excessive quantity of effete products, such as urea and other matters related to urea in composition, some or all of which are poisonous to the system in a greater or less degree. So long as these are freely eliminated by the emunctories, the blood may remain fairly pure, and little mischief ensue. We have shown, however, that this elimination is sometimes arrested temporarily. There is no doubt that it is often insufficient to effect the purification of the blood. Under such circumstances uræmic poisoning and typhoid symptoms are only too apt to usher in a fatal issue.

The persistence of a temperature above a certain elevation is incompatible with the maintenance of life. It has been shown by the experiments of Delaroche and Berger that animals, placed in an atmosphere ranging from  $122^{\circ}$  to  $201^{\circ}$  until the heat had killed them, were found at the time of death to have an internal temperature of only  $11^{\circ}$  to  $13^{\circ}$  above their natural standard; whence it may be inferred that an elevation to this degree is necessarily fatal to them. We do not, of course, know with accuracy what is the upper limit of temperature which is compatible with the maintenance of life in the human being. We may say, however, with some degree of assurance, that a persistent temperature above  $110^{\circ}$  will certainly cause death, and that there is good reason to believe that a temperature of even  $107^{\circ}$  cannot be supported for any length of time. Death from high temperature is attributed by Bernard to a condition of the heart analogous to rigor mortis; the auricles are found full of blood, the ventricles contracted and empty. The injurious influence of excessive heat, however, is not exerted on the heart alone, but equally on all living tissues, and especially, probably, upon simple protoplasm wherever it is distributed. In cases of hyperpyrexia, the symptoms referrible to the nervous system are particularly striking. They usually commence with restlessness, confusion, and tendency to mental disturbance, and lead, through maniacal excitement, muttering delirium, or convulsions, to coma and death. Nevertheless, it is by no means clear to what extent these symptoms are referrible to abnormal heat. It is a remarkable fact that frequently, when the advent of death is attended with rising temperature, the heat of the internal parts continues to increase for some hours after death.

It will be readily gathered from the foregoing discussion that the immediate cause of febrile temperature lies in the excessive degradation of the tissues of the organism, and the consequent evolution of their latent heat.<sup>1</sup> The abnormal activity of circulation and respiration, which accompanies fever, alone implies unwonted activity in some at least of the processes which these functions subserve; and the progressive emaciation of the frame and the continued over-discharge from the lungs of carbonic acid, and presence in the urine (notwithstanding, in many cases, almost total abstinence from food) of an excessively large quantity of those matters which are the result of the degradation of albuminous compounds, clearly demonstrate the character of these processes. This explanation obviously does not touch that further important question, 'What is the cause of the tendency, which is always present in fever, to that preternaturally rapid destruction and oxidation of tissue on which the febrile elevation of temperature

<sup>1</sup> It has been suggested by Dr. Ord that febrile temperature is due, at least in part, to the diminution or cessation during fever of those constructive processes which in health presumably cause heat to become latent; and by Dr. Thudichum that, under the influence of the processes of fever, there may be a shrinking of tissues with evolution of latent heat, and hence elevation of temperature above that due to disintegration alone. It may also be that in the febrile state certain chemical compounds or hydrates are found, in the formation of which evolution of heat occurs. But at present these are mere hypotheses.

depends?' This question, notwithstanding its importance, we shall not venture to discuss. There can be no doubt, however, that the thermogenic centre directly or indirectly exercises a large though variable influence over the intimate processes on which febrile heat depends. And indeed there are certain cases, as for example that of hyperpyrexia in rheumatism, and especially functional nervous disorders, attended with occasional or long-continued high temperature, in which, so far as we can judge, the processes on which the febrile heat depends are set going and kept up by the spontaneous or afferently excited influence of this centre.

iii. *Hectic fever*.—The term 'hectic' is applied to those varieties of fever that attend various diseases of long duration, and more especially such affections as malignant disease, tuberculosis, and chronic syphilis, which are characterised by the gradual development of proliferating growths in many organs, or such as caries of bones, disease of joints, and the like, in which purulent discharges are kept up for an indefinite period.

The phenomena of hectic fever are essentially those which have been described in the preceding account of fever. They are chiefly peculiar in their comparative mildness and long duration. The symptoms of hectic come on insidiously, and the febrile condition may be already far advanced before its presence is fully recognised. The patient probably finds himself gradually losing flesh and strength, and becoming disinclined for exertion. He observes that he is disposed to be chilly in the morning; that in the evening, and in a less degree after meals, his hands and feet are hot and dry, and his face flushed; and that he wakes towards the morning with a moist perspiring skin. But his tongue is clean, his appetite good, and, although he may be thirsty and his pulse quickened, his functions generally are properly discharged. At this time a careful thermometrical examination will probably show his temperature to be elevated by two or three degrees; but also that, as in health, it is lowest in the morning and highest in the evening, and that his indistinctly developed cold, hot, and sweating stages correspond pretty accurately with the usual cycle of the healthy temperature-variations.

As the morbid condition on which the fever depends progresses, the symptoms (although of the same character as before) get more distinctly developed, the patient becomes pallid, his emaciation and debility more obvious, and the febrile character of his illness more striking. The temperature, even now, often does not exceed  $103^{\circ}$ ; but it is liable to occasional higher degrees of elevation, and in its matutinal remissions may sink below the normal. The patient is apt to be chilly in the morning, with cold and livid feet, hands, and nose. In the evening exacerbation the skin gets hot and dry, the palms and soles burning hot, the lips dry and red, and the cheeks flushed with a circumscribed red flush; and towards the morning he wakes to find himself drenched in profuse (colliquative) perspirations. The chief exacerbation occurs almost invariably in the evening, and it is often the only one; but there is occasionally a second, earlier in the day; and generally the ingestion of food, and especially of an ample meal, is

followed by febrile reaction. With the progress of the other symptoms, the pulse becomes accelerated; and even if it feels sharp, as it may do during the febrile exacerbations, it is positively enfeebled, and undergoing progressive enfeeblement. Even now, probably, the tongue is clean, perhaps morbidly clean, and the appetite good. There is, however, thirst, the bowels probably are constipated, and the urine (especially in the febrile paroxysms) is scanty, high-coloured, and concentrated.

At a later stage the symptoms are modified, and other phenomena (not wholly referrible to the fever) superadded. The emaciation and debility get extreme, the pulse more and more feeble and rapid, the circulation imperfect; bed-sores form; the fingers grow livid and bulbous, and the skin harsh and scaly; diarrhoea not unfrequently supervenes; the tongue gets dry and fissured or aphthous; the appetite fails; and death from exhaustion presently ensues.

It is remarkable that the intellect is rarely affected, and that, in a large proportion of cases, the patient continues cheerful and hopeful even to the last.

iv. The *thermometer* of late years has become to the physician almost as important as the stethoscope. It is in general use, and is certainly of extreme value, not only in the diagnosis, but in the prognosis of disease. It is desirable, therefore, to make a few observations in reference to it. A clinical thermometer should be accurate and sensitive, should have its degrees divided into fifths, and be so marked as to be easy of perusal. It should be furnished with an index, consisting of a single fragment of mercury, between one-fourth and one-third of an inch long, detached from the upper part of the mercurial column. For ordinary use an instrument, which may be carried in the waistcoat pocket in a case, and marked from  $95^{\circ}$  to  $112^{\circ}$ , is sufficient. It is well, however, to be provided, for special purposes, with a thermometer of greater range (say from about  $80^{\circ}$  to  $112^{\circ}$ ), and probably, therefore, of greater length, and comparatively cumbersome. The index should never be allowed to descend into the reservoir, and so to mingle with the rest of the mercury; nor should supplementary indices be allowed to detach themselves from the mercurial column. The former accident may be prevented by never violently shaking the index into the reservoir, and to some extent by the presence of an annular constriction in the channel of the thermometer a little above the reservoir; the second, by always carrying the thermometer horizontal or with the reservoir downwards, and by never permitting the mercury when it has risen into the tube to be too suddenly cooled. Prior to taking a temperature, the index should be brought into the lower part of the tube, at least below the mark indicating the lowest temperature we are likely to meet with. The bulb of the instrument should then be placed in the part selected (in the axilla, beneath the tongue, in the anus or vagina), and retained there sufficiently long to permit of the rise of the mercurial column, and the carriage of the index, to the position corresponding to the temperature of the part. It is important, especially as regards the axilla, that the bulb of the instrument should be tightly grasped, and entirely

protected both from the influence of the air and from the contact of the clothes, and that it should be allowed to remain *in situ* from three to five minutes at least. A casual observation is of course often of considerable value; in many cases, however, and especially in fevers and inflammations, periodical observations should be made. Sometimes morning and evening determinations of the temperature are sufficient for all practical purposes. But not unfrequently, especially in very severe and acute diseases, in certain specific diseases, or when the effects of particular forms of treatment are under investigation, periodical observations of much greater frequency are called for.

*d.—The typhoid condition*

The condition here referred to, like fever, is common to many different diseases. When erysipelas, carbuncle, pneumonia, or any other severe inflammation, is tending to a fatal issue; in the later stages of typhus, enteric fever, scarlatina, small-pox, and other specific fevers; towards the fatal close of acute atrophy of the liver, and of uræmia consequent on Bright's disease; and at the corresponding period of many other affections; typhoid symptoms, or symptoms resembling those of the later stages of typhus fever, are apt to supervene.

The patient becomes prostrate; he lies on his back in bed, with eyes closed, features shrunken and ghastly, and a dull stupid aspect, unconscious, or nearly unconscious, of everything that is going on about him. His skin is dusky, moist, and sometimes bathed in sweat, which often yields a fetid odour, and is for the most part, especially in the extremities or exposed situations, cold. His lips are dry, black, and probably fissured, his teeth loaded with sordes, his tongue dry brown or black, and often contracted in all its dimensions. He has no inclination for food, and probably no material thirst, but he has a difficulty (partly due to the condition of his mouth) in swallowing and utterance. His bowels are sometimes constipated, but often relaxed, and the evacuations are apt to be offensive. His respirations are shallow, but for the most part not much accelerated—ranging probably between twenty and thirty in the minute. They may, however, be much more frequent, and are liable to variation. The pulse is rapid and feeble, and tends to get more and more rapid and feeble, and, towards the end, imperceptible at the wrist, and irregular. It may vary at first from 100 to 120, but often attains a frequency of 140 or more, and at the same time assumes an undulating dicrotous character. The first sound of the heart is liable to become inaudible. Shortly before death, the superficial capillaries often dilate, the blood accumulates and stagnates within them, the surface acquires a rosy aspect, and a profuse flow of perspiration takes place. Bed-sores are apt to form upon the sacrum and other parts exposed to pressure. The condition of the urine presents considerable variety:—sometimes it is scanty, high-coloured, and loaded with urates; sometimes it is abundant, pale, and limpid, and of low specific gravity. Muscular debility is shown in the tendency which the patient has to lie

upon his back, and to sink towards the bottom of the bed. His senses are blunted; often he is deaf; he takes little notice (even if his eyes be open) of surrounding objects; he rarely complains of pain or uneasiness, or acknowledges its presence, and is insensible to conditions which at other times would have caused much personal discomfort; his intelligence is impaired, especially his memory fails; his mind is full of delusions, and he is more or less constantly muttering—he is in a condition of ‘low muttering delirium’ or *typhomania*; he can probably, however, be recalled to himself momentarily if addressed loudly, and will then half-open his eyes, endeavour to do what he is told, and even give an intelligent response; but he soon lapses into the state from which he was aroused; he picks at the bed-clothes; his limbs are tremulous when he endeavours to use them, and his muscular fibres are in constant vibratile movement giving rise to the condition known as *subsultus tendinum*; he passes his evacuations unconsciously, or allows the urine to accumulate in his bladder. With the advance of the typhoid symptoms, the mind becomes more and more obtuse, and the patient gradually passes into stupor, and thence into profound coma. The temperature presents great variety, dependent in a considerable degree on the nature of the disease upon which the typhoid symptoms supervene; sometimes, as in Bright’s disease, it is a good deal below the normal standard; sometimes, as in the hyperpyrexia of acute rheumatism, it attains an elevation of  $110^{\circ}$  or more. The typhoid condition is always one of great gravity, and in a large proportion of cases terminates in death.

The collective phenomena of the typhoid state have generally been attributed to the presence of some poisonous matter in the blood. Formerly this was believed to be the specific virus of the disease in the course of which they were developed; or, in the case of local inflammations, some morbid elements generated at the diseased spot and thence thrown into the circulation. It is difficult, however, to understand how it can happen that numerous poisons, distinct from one another, and having different actions in other respects, should yet have the common property of inducing the complex phenomena of the state under consideration. Another view is now commonly entertained, and has higher claims to acceptance. It is to the effect that the poisonous matters which circulate in the blood are not the specific elements of diseases, but those products of the disintegration of nitrogenous tissues which are known, when accumulated in the blood, to have poisonous effects; and which are apt to accumulate in the blood in all those diseases in the course of which typhoid symptoms supervene. The excessive production of such effete matters in various local inflammations, and in the infectious fevers, is an established fact. And as regards some of the latter diseases, it has been distinctly proved, not only that the kidneys (even when healthy) often fail to eliminate them in normal quantity, but that even when these organs excrete them profusely, the blood still remains overloaded with them; and further that, in such patients, when they die with typhoid symptoms, urea in excess is discovered in the blood. In chronic Bright’s disease there is the same

accumulation of urea and such like matters in the system; and the typhoid symptoms which come on in its course have long been regarded as of uræmic origin. The above considerations make it probable that typhoid symptoms, whether they occur as a complication of Bright's disease or come on in the course of febrile disorders, are due to the same cause, namely the poisonous operation of excess of effete matters in the blood. The circumstance that this excess is due, in some cases, to over-production, in others to retention, does not tend in any degree to invalidate this conclusion.

*e.—Collapse. Syncope*

The states of collapse and syncope are in many respects the opposite of that of fever, and are attended with either general or partial loss of temperature. It is important, however, to observe that a general depression of the temperature of the body may take place, without any of the other symptoms of collapse being present, especially during the remissions of various febrile disorders, or the periods of convalescence from them; and that, on the other hand, profound collapse may occur while the temperature of the internal organs is still many degrees above the normal.

The conditions under which collapse or syncope may come on are very various. It may occur in the cases above mentioned—namely, in the periods of remission of fevers, or during convalescence from them; it may come on in rigors, or when (as in cholera) a high internal temperature prevails; it may be consequent upon the presence of urea, or of extraneous poisons, in the blood. Other causes are mental emotions, more especially such as are of a depressing character; sudden and excessive pain; unwonted distension of tubes (the urethra, the ureters, and the bile-passages to wit) by foreign bodies; rupture or perforation of internal organs; hemorrhage and profuse discharges, especially from the bowels; vomiting; severe injuries of all kinds, including those due to the operation of irritant substances or poisons upon the stomach; mechanical obstacles to the cardiac circulation; and many others.

The symptoms of *collapse* are mainly the following:—coldness and pallor of surface, more especially of the extremities and face, which appear shrunken, pinched, and occasionally livid; perspiration more or less profuse, sometimes limited to the extremities and face, and generally forming large drops in the latter situation; infrequency of the respiratory acts, which are shallow, sometimes scarcely perceptible, often irregular, and now and then sighing or gasping; feebleness of heart's action, indicated sometimes by increased frequency, sometimes by slowness, of the pulse, which often becomes irregular and often scarcely perceptible, or imperceptible, at the wrist; occasionally hiccough and nausea, or even vomiting; extreme muscular debility; noises in the ears, indistinctness of vision, general soreness or sense of compression, want of breath, giddiness, depression or anxiety, and confusion of thought. In some cases there is restlessness, transient delirium or maniacal excitement, occasionally attended by convulsions, or complete insensibility; in some cases, on the

other hand, the mental condition is wholly unimpaired from first to last. In severe cases the patient lies almost motionless, with eyelids half closed and perhaps slightly twitching—looking like a corpse. In true collapse there is probably always more or less marked fall of temperature; and that is the case even when, as in the collapse of cholera and other febrile disorders, the internal temperature is still abnormally high. But in all cases the extremities and the head lose heat rapidly, and usually become positively cold. In cholera, the thermometer in the mouth or axilla may stand at  $90^{\circ}$  or less, while that in the rectum marks  $105^{\circ}$ ; and in collapse, the result of severe injury, the temperature even in the rectum may fall (as is shown by Mr. Wagstaffe) as low as  $82.15^{\circ}$ . Much more commonly, however, collapse-temperatures range between  $92^{\circ}$  and  $97^{\circ}$ .

*Syncope* differs from collapse (of which indeed it is a mere variety) mainly in the suddenness of its access and the rapidity of its progress, but generally also in the fact that the symptoms of syncope, during their continuance, are more severe than those of collapse. This latter distinction is, however, by no means essential; for, as is well known, syncope may present all degrees of intensity, from a simple sense of faintness to a prostration so profound as to simulate death. The short duration of syncope necessarily precludes the occurrence of any marked depression of the general temperature.

When recovery from collapse or syncope takes place, there is always more or less reaction; the surface gets smooth, its colour returns, and a general glow supervenes, the circulation revives, the temperature rises, and other febrile phenomena manifest themselves. And if the collapse have been profound and of long continuance, the consecutive fever may assume serious proportions.

In considering the pathology of collapse there are three factors of that condition the importance of which is especially obvious. These are depression of temperature, feebleness of circulation, and the condition of the nervous functions. First: the depression of temperature, so far as regards the limbs, face, and other exposed parts, can no doubt be traced mainly to the comparative failure of the circulation in them. But that this is not the sole cause of that depression is obvious from the fact that the internal temperature, instead of rising, as under such circumstances it should normally do, itself tends to diminish, and sometimes diminishes rapidly. It is clear indeed that there is throughout the organism a more or less complete arrest of those disintegrating processes upon which the maintenance of the temperature of the body depends, and presumably also a more or less complete arrest of those vital processes with which these latter are intimately interwoven. Second: the feebleness of the circulation is shown by the obvious weakness, and frequent irregularity, of the heart's action, by the failure, more or less complete, of the pulse at the wrist and in other peripheral situations, and by the concurrent disappearance of blood from the cutaneous surface and other textures. The details of the processes by which the failure of the circulation is induced doubtless differ in different cases. It may, however, be assumed that there is

always cardiac debility, and in a large proportion of cases diminished supply of blood to the left side of the heart, and hence to the vessels which it supplies. In collapse from hemorrhage the latter condition is of extreme importance. And, indeed, it is found, in a large proportion of cases of death from syncope or collapse, that the cavities of the right side of the heart are distended, while those of the left side, and more especially the ventricle, are contracted and empty. In other cases, however, (especially if death has been sudden), the left cavities may be found overloaded. Third, and most important, is the condition of the nervous functions. We have pointed out the not unfrequent dependence of collapse or syncope on affections of the mind, and on many other conditions which can be operative only through the medium of the nervous system; and we have enumerated the various phenomena referrible to the nervous system, which attend and characterise a large proportion of cases. These facts are sufficiently suggestive. But when we look a little more closely into the matter, and consider how many different causes, of different operation, equally produce the same collective phenomena of collapse; how rapidly these phenomena come on, and how universally the organism is affected by them; how impossible it seems that a smash of the leg, a perforation of the bowel, or an agony of terror, should directly arrest the chemical changes going on throughout the organism, and so reduce the temperature of the body, or should directly influence the action of the heart and arteries, it is impossible to doubt (what many other considerations tend to prove) that all the phenomena of collapse are directly traceable to the operation of the nervous system—not, however, of the brain or cord, but of that department, namely the sympathetic, which presides over circulation, nutrition, and the functions of the various organs, including those of the brain itself.

#### *f.—Death*

Death is one of the natural terminations of disease; and according to the nature of the disease, or the office, bulk, or position of the organ which may be its seat, the phenomena which usher in that event differ in a greater or less degree. Many of the specific fevers prove fatal with the supervention of typhoid symptoms; many exhausting diseases cause death by simple debility or asthenia, and other affections by the allied conditions of syncope or collapse; diseases of the air-passages or lungs prevent the due aëration of the blood, and are fatal by asphyxia; renal affections lead to the accumulation of urea in the blood, and death by so-called ‘uræmic’ poisoning; and diseases of the brain induce coma, from which death presently results. In a large proportion of cases, no doubt, various morbid processes concur in the induction of the fatal issue. Nevertheless, a careful consideration of the phenomena of death enables us to bring the different modes of dying, numerous as at first sight they may appear to be, into a comparatively small number of distinct groups.

Bichat, in his ‘Recherches sur la Vie et la Mort,’ speaks of ‘death beginning at the head,’ ‘death beginning at the heart,’ and ‘death begin-

ning at the lungs.' It is obvious, however, that these are not the only organs from which death commences; and even those who follow Bichat most closely find it necessary to adopt his views with some modification or addition. To us it appears that the principal sources of somatic death are to be found: first, in failure of nutrition; second, in failure of the circulation of the blood; third, in failure of the emunctories to effect the elimination of effete and poisonous matters; and, fourth, in failure of the nervous system to perform its proper functions.

i. *Death from failure of nutrition.*—This may be due to many circumstances, and may arise in the course of many diseases. It may depend on actual deprivation of food, as in simple starvation, or in obstructive disease of the œsophagus or cardiac orifice of the stomach; or on persistent vomiting or diarrhœa, or any other affection (structural or functional) of the alimentary canal, which interferes with the due absorption of nutritious matters at the mucous surface; or on the presence of diabetes, or of rapidly growing malignant tumours, in which there is a misappropriation of the nutriment received into the blood; or on the presence of inflammatory processes, or febrile disorders, in which excessive waste of tissue takes place without equivalent reconstruction; or, lastly, it may be referrible to the continuance of wasting discharges or losses of blood. The symptoms which precede death in these several cases depend largely upon the special conditions under which they arise, and are therefore liable to considerable variety. But such as are peculiarly referrible to innutrition are, more or less rapidly increasing emaciation and debility, mental languor, feebleness of circulation, and inability to resist the influence of external cold. The general emaciation is not always proportionate to the muscular debility, which, after a while, becomes extreme. The patient probably lies on his back, motionless or almost motionless, with hands, feet, nose, and ears more or less cold and dusky; breathing feebly and at long intervals, with the pulse barely perceptible at the wrist; sensible, but dull and languid, taking little notice, and not even caring to restrain the escape of his evacuations. With possibly no addition to the symptoms, the general feebleness passes almost insensibly into death—the last indication of life being furnished by the barely perceptible movements of the heart. In simple starvation there is a general lowering of temperature, which previous to death becomes considerable. Here life may sometimes be maintained for a while by the application of warmth. In disease, however, although loss of temperature is not unfrequent, rise of temperature, under certain circumstances, is of common occurrence.

ii. *Death from failure of the circulation.*—The failure may commence in various situations, may arise from many causes, and may come on with different degrees of rapidity. It most commonly takes place at the heart, which ceases to propel the blood; either from actual inability or failure to contract upon its contents; or from spasmodic contraction which opposes the entrance of blood into it; or from the compression exerted upon it by accumulation of serum or blood in the pericardial cavity; or from the obstruction of one of its orifices by clot, or some other equivalent cause.

It may also depend upon obstruction of the pulmonary arteries by thrombosis or embolism ; or upon general contraction of their smaller branches, as occurs in asphyxia ; or upon similar contraction of the smaller systemic arteries, as probably happens in angina pectoris. Death from the causes here referred to may take place quite suddenly—the patient fainting and falling down insensible, and with a gasp or a convulsive tremor yielding up his breath. It may take place less suddenly, yet still rapidly—the victim getting pale, cold, bedewed with sweat, insensible or nearly so, and possibly convulsed, with slow and shallow or gasping respiration, extreme feebleness of the heart's action and imperceptible pulse. When the process of dying from failure of the circulation assumes a more chronic form, the phenomena of collapse are doubtless always present in some degree, and there is more or less obvious disposition to depression of temperature ; but, in addition, the blood tends to accumulate and to stagnate in the capillaries and veins ; dropsy and congestion, with extravasation of blood, are apt to take place ; and not unfrequently the parts furthest removed from the influence of the heart (nose, fingers, toes) become gangrenous. Certain differences in the details of dying depend, no doubt, on the situation in which obstruction occurs. It is stated that, if it take place suddenly on the right side of the heart or in the trunk of the pulmonary artery, extreme dyspnoea is one of the prominent symptoms. If, on the other hand, the sudden obstruction occur on the left side, insensibility and convulsions will probably be amongst the earliest of its consequences. Further, if gradual impediment arise on the right side of the heart or in the course of the pulmonary artery or its branches, more or less over-accumulation of blood will speedily ensue in the systemic veins and capillaries ; if such impediment arise on the left side of the heart, the consequent congestion will first involve the pulmonary vessels.

iii. *Death from failure of the elimination of effete and poisonous matters.*—The poisonous matters, to which reference is here specially made, are those which accrue in the course of the disintegrating and excretory processes which are always going on, and are mainly, therefore : carbonic acid, which is evolved by the lungs ; urea and other nitrogenous matters, which are discharged by the kidneys ; and some of the constituents of the bile, which are formed in the liver and under certain circumstances absorbed into the circulation. Among these must especially be included certain alkaloidal substances, of which our knowledge is only in its infancy, and which are formed in the body under conditions of great obscurity.

The retention of carbonic acid in the blood produces the condition which is commonly known as asphyxia, but might perhaps be better designated anthracæmia. It may arise in various ways :—from obstruction of the larynx or trachea ; from bronchitis or other affections causing block of the bronchial tubes ; from disease of the lungs ; from mechanical impediment to respiration, due to accumulation of fluid in the pleural cavities ; from paralysis or spasm of the respiratory muscles ; or from deficient supply of atmospheric air. The symptoms of sudden asphyxia

are manifested in their typical completeness in cases of drowning, or of choking from the intrusion of a solid mass into the upper part of the larynx. The sense of dyspnœa is extreme, and violent but futile respiratory efforts take place. But soon vertigo comes on, the respiratory agony diminishes, and the efforts at inspiration get less violent. Gradually unconsciousness supervenes, convulsive movements may occur, and in the course of a few minutes all muscular action ceases. The heart continues to beat, perhaps for a minute or two, after respiration has come to a standstill. During the progress of suffocation, the non-arterialised blood is impeded in its transit both through the small arteries and capillaries of the lungs, and through the corresponding systemic vessels, and the pressure of blood in the systemic vessels becomes augmented. But gradually, the obstruction getting more and more complete in the vessels of the lungs, less and less blood reaches the left cavities of the heart, and consequently less and less is propelled into the arteries, which also by gradually contracting on their contents drive them slowly onwards into the veins. Thus, while the pulmonary veins, left cavities of the heart, and systemic arteries become comparatively empty, blood is gradually accumulating in the pulmonary arteries, right side of the heart and systemic veins and capillaries, and the general surface gets more and more livid and swollen, and the superficial veins more and more obviously distended. But poisoning by carbonic acid takes place much more gradually in the course of many diseases, and may extend over a period of many months. The general phenomena, in such cases, are essentially the same as those just detailed, but they are, as it were, more diluted and of less intensity. The surface gets dusky or livid and cool, the veins distended, the right side of the heart dilated, the pulse quick, feeble, intermittent; there is more or less distressing dyspnœa and anxiety; but gradually the struggle for breath grows less painful and violent, the patient gets drowsy and rambles, and then passing into a condition of coma and general debility gradually sinks.

The accumulation in the blood of urea and other matters, which should be eliminated by the kidneys, leads to many important consequences. By their slow action they induce anæmia, contraction of the smaller systemic arteries, hypertrophy of the heart, and dropsy, with, sooner or later, impairment of the nervous functions, and especially delirium, eclampsia, and coma. It is to them also that are mainly due the collective phenomena, to which the name of 'typhoid condition' has been given, and which (as has been already pointed out) are apt to come on in the course of various febrile disorders and in structural diseases of the kidneys.

iv. *Death from failure of the nervous system to perform its proper functions.*—Diseases of the nervous system are fruitful sources of death. Coma is not only a frequent precursor of death in cases in which the brain is not primarily involved, but it is a common symptom of grave cerebral lesions. In coma there is profound unconsciousness, the patient breathes slowly, irregularly, and stertorously, the saliva and other secretions from his mouth, throat, and air-tubes accumulate in these several

passages, and are not expelled; and gradually, partly from this cause, partly from failure of the respiratory muscles, he dies of asphyxia. Again, spasm, or motor paralysis, may equally produce death by asphyxia; in epilepsy spasm of the glottis, in tetanus spasm of the muscles of respiration, may stop the breath and asphyxiate the patient; and the like result may ensue from paralysis of the muscles of the throat and larynx, or of those that govern the movements of the chest. But in these cases it is obvious that, although death may be said to begin from the brain and cord, the patient dies in reality of carbonic acid poisoning. In truth, however, it is not the brain and cord, but the sympathetic system of nerves which has the direct control over the functions, the sum of which constitutes life. It is this which has within its grasp, so to speak, the whole of the circulatory system, the excretory, secretory, and nutritive processes, and even the functions of the brain itself; and it is to this system, therefore, that we should especially refer when we speak of death commencing from the nervous centres. It is to the influence of this system that both paralysis and spasmodic contraction of the heart and blood-vessels are due; it is to the influence of this system alone that the phenomena of shock or collapse (which have been previously described) are directly referrible.

Now, although, in the foregoing paragraphs, we have distinguished several modes of dying, or groups of processes by which death is induced, it is obvious, if we come to compare them among themselves, that they have much in common, and tend to shade the one into the other. Thus, death from coma, or tetanic spasm, resolves itself eventually into death from asphyxia, and death from asphyxia into death from arrest of the circulation of the blood, and this arrest of the circulation of the blood into spasmodic and insuperable contraction of the pulmonary arterioles, which in its turn is referrible to the influence of the vaso-motor nerves. And, indeed (excepting probably those cases in which death is induced by the sudden cessation of the heart's contractions under the influence of shock), the last obvious efforts of life are those of the heart: the patient becomes unconscious; the respiratory efforts cease; yet still we listen for the sounds of the heart, and only when these finally disappear consider life extinct. But in neither shock nor asphyxia does the heart (at all events as a rule) cease to act because its muscular parietes have wholly lost their aptitude for contracting. In the former case, the heart is, as it were, stunned, and may yet, under the influence of artificial respiration, have its movements re-established; and in the latter case, where the heart seems to cease from sheer debility, this debility is rather in the ganglionic centres and nerves, which fail to supply the accustomed stimulus, than in the muscular tissue itself, which may still be made to contract under the influence of artificial stimulation. Hence it would seem that while, as a rule, the cessation of the heart's beats may be regarded as the last observable phenomenon of life, this cessation, as well as that of many other phenomena of organic life, may in their turn be referred to the sympathetic system.

## V. THE TREATMENT OF DISEASE

DETAILS of treatment are discussed, with more or less fulness, under the heads of the various maladies which are described later on in this volume. There are, however, some general principles involved in the treatment of disease which it will be convenient to touch upon briefly here. They come mainly under the heads of 'Hygiene,' 'Prophylaxis,' and 'Remedial Treatment.'

A. *Hygienic Treatment*

By the term *Hygiene* is meant the science of health, or the study of those conditions on which the maintenance of health depends. Hygiene, therefore, takes cognisance: of the sanitary influences of the atmospheric and telluric circumstances among which we dwell; of the conditions, in relation to density of population, ventilation, drainage, cleanliness, and the like, in which we live; of the quality of the water and food we swallow; and also of our dress and personal habits. The immense importance of attention to this department of medicine is beyond dispute; yet the subject is so vast, and the details which it involves are so numerous, that it would be out of place to engage in their discussion in such a work as the present.

But attention to the laws of hygiene is not less important for the welfare of the sick and convalescent, than it is for the welfare of those who are as yet in the enjoyment of good health; and, indeed, it not unfrequently happens that it is to hygienic measures, rather than to drugs, that we must look for the cure of our patients. Even in this restricted sense, the subject of hygiene is too extensive to admit of satisfactory discussion within the limits of space at our disposal. It must be sufficient (by way of example) to refer: to the important beneficial influence which a mild balmy air exerts upon those who are suffering from inflammatory affections of the respiratory organs, or from pulmonary phthisis, and upon convalescents from many different diseases; to the injury which cold winds or variable weather inflicts on rheumatic patients; to the essential importance of treating the sick in airy, well-ventilated apartments, and of yet securing an equable genial temperature, of maintaining perfect cleanliness of the patient's person and of everything around him, of removing at once from his chamber all evacuations and other offensive matters, and of taking care that the water he drinks is free from unwholesome impurity, and the food he takes is of good quality; and as regards those who are suffering from illnesses which do not necessitate confinement to the house, or those who are recovering, to the need for seeing that their dress is sufficiently protective against the weather, that they are not intemperate in meat or drink, and that they do not keep bad hours, or indulge in any other habits which are or may be hurtful.

But different diseases are obnoxious to different injurious influences,

and hence modifications in the employment of hygienic measures are needed for different cases. But these are points which, so far as is necessary, will be dealt with subsequently.

### B. Prophylactic Treatment

By *Prophylaxis* is signified the preventive treatment of disease. In some respects this subject may be regarded as a part of hygiene, in some as a part of ordinary remedial treatment. We prefer, however (mainly for convenience of discussion), to look upon it as distinct from both. We understand by it the adoption of special measures to prevent the outbreak of special diseases which threaten, or the supervention of anticipated dangers in the course of diseases, and shall briefly consider it under the following heads :—

1. *Prophylaxis in relation to the tendency, inherited or acquired, to disease.*—We know that many persons derive from their parents proclivities towards certain diseases, such as phthisis, gout, epilepsy, and insanity. We know also that many of these affections may be induced, in those who are free from taint of inheritance, by circumstances which tend to impair the general health. We know, further, that exposure to similar conditions is peculiarly apt to act injuriously on those in whom such tendencies already exist. And hence the importance, which is fully recognised, of adopting precautionary measures in reference to such persons ; of sending the patient, in whom phthisis threatens, to an equable climate ; of restricting the diet, and especially of curtailing the alcoholic drink of him who has reason to anticipate gout ; and similarly with reference to many other affections. Again there are many diseases of which one attack imparts a liability to subsequent attacks : such are rheumatism, erysipelas and other inflammations, and ague. It is obvious here, again, that it is of the utmost importance, for the welfare of the patient, that he should be protected from those injurious influences which he knows by experience to be the sources of his malady.

2. *Prophylaxis in relation to parasitic, endemic, and infectious diseases.*—Many parasitic diseases are developed under circumstances which are well understood. Tape-worms are derived mainly from the use of the insufficiently cooked flesh of oxen and pigs, and the trichina spiralis from the ingestion of that of the latter animal ; the Guinea-worm and the bilharzia both prevail in certain regions. It is needless to dwell on the importance which the knowledge of such facts has in reference to the prevention of maladies of this kind. Endemic diseases are due to the operation of local causes, a knowledge of the behaviour of which, or of their distribution, clearly furnishes an important clue to their prevention. Thus ague prevails in certain regions, goitre and cretinism in others ; and in both instances the occurrence of disease may be prevented by removal to some more salubrious district. In the former case, indeed, the malarious poison may be eliminated or destroyed by effectual drainage. Amongst endemic affections may be included ergotism from the use of

spurred rye as food, and lead-poisoning from drinking lead-infected water; the suitable prophylactic measures against which are sufficiently obvious. Epidemic diseases are probably always directly or indirectly contagious; but the several poisonous matters or contagia, to which their spread is due, are thrown off from different parts of the organism, gain entrance into the system by different portals, and present in other respects essential differences of habit. The knowledge that the contagium of typhus becomes especially virulent in the presence of overcrowding, and that that of relapsing fever has some peculiar relation with starvation, is of great importance in reference to the measures which should be adopted in order to prevent the development, or arrest the spread, of these diseases; the knowledge also that measles is in the highest degree contagious previous to the occurrence of the rash, and that scarlet fever is comparatively little contagious during the corresponding period, or even for a few days subsequently to the appearance of the rash, is of importance also in reference to the management of these affections. Again, the knowledge which we now possess that, while most of the exanthemata are propagated through the atmosphere by the breath or cutaneous emanations, cholera and typhoid fever are infectious only through the intestinal excreta, and their poisons received into the system mainly by means of contaminated drinking-water, supplies us with practical data of the highest value as to the methods by which their outbreaks should be dealt with. The fact that in most of the diseases coming within the epidemic class, one attack is protective in a greater or less degree against future attacks, is also of great importance in relation to prophylactic medicine.

3. *Prophylaxis in relation to the complications or sequelæ of disease.*—Most diseases bring in their train liabilities to specific incidents of more or less gravity—a fact the appreciation of which enables us in many cases to take early measures for their prevention or alleviation. The knowledge that rheumatism is apt to involve the pericardium or valves of the heart; that, in scarlet fever, renal inflammation, albuminuria, and anasarca are liable to supervene; that in enteric fever perforation of the bowel may take place at certain stages of the disease; that in gonorrhœa the eyes may get infected and destroyed, enables us, in dealing with these affections, to take precautions which are often successful against the supervention of the mischances which have been enumerated.

### *C. The Remedial and Therapeutical Treatment of Disease*

The great aim of medical art is the cure of disease. Unfortunately, however, a direct cure (at all events a direct cure by means of drugs) in the great majority of cases is totally impossible. In some parasitic affections, and more especially in such as involve the surface of the body, we may kill or expel the parasites, and so restore the patient to health; by surgical operation or other mechanical measures we may get rid of foreign bodies or concretions from internal cavities or canals, remove diseased parts, discharge the accumulated contents of normal or abnormal cavities,

reinstatement of displaced organs, dilate contracted channels, or, failing this, make new openings above the seat of obstruction, and so provide passages for the habitual escape of matters that need evacuation; and we may, in a small number of cases, by the use of specific medicines or diet, materially alleviate, and even cure absolutely, certain diseases: by arsenic or quinine ague, by mercury syphilis, by colchicum gout, by iron chlorosis, by fresh vegetables scurvy, and by suitable food, possibly rickets and some other affections. But neither by mechanical measures, nor by specific drugs, nor by the restoration to the dietary of matters in which it has been wanting, can we cure the infectious fevers, internal inflammations, carcinoma, degenerative changes, or many of the functional and other disturbances to which the organism is liable. Most of these affections, indeed, take a course peculiar to themselves, tending in some cases to ultimate recovery, in some to chronic ill-health, in some to speedy death. We can do little, often nothing, to arrest them in their progress, or to put limits to their duration. And frequently all that remains to us is, by maintaining the patient's strength, by relieving symptoms and by taking precautions against the supervention of complications or accidents, to enable him to pass with comparative safety or comfort through his malady—hastening convalescence if the disease be one that does not necessarily end fatally, postponing the final issue if the disease be in the nature of things mortal. The chief general indications under such circumstances seem to be:—1st, to promote the patient's general comfort; 2nd, to support his strength by appropriate nourishment; 3rd, to maintain or to restore the healthy tone of his nutritive functions; 4th, to promote the free action of his excretories; 5th, to relieve the secondary phenomena or symptoms of his disease; and 6th, to obviate the tendency to death.

1. The rendering the patient's condition as comfortable as circumstances permit involves of course careful and judicious nursing, and the closest attention to all hygienic and other details of management. The latter will necessarily differ in different cases; but, in illustration of our meaning, we may signalise the following points:—keeping the room dark in eye-diseases, or where it is important to promote sleep; maintaining quiet where in brain diseases and other affections there is acoustic hyperæsthesia; soothing the patient when he is irritable or excited; raising his hopes and spirits when he is depressed or desponding; and when he is in a condition to enjoy such pleasures, to gratify, without worrying, his mind with pleasant surroundings and diversions. It need scarcely be added that patients should always be kept as clean, dry, and free from undue pressure or friction as possible, and should not be allowed to soak in their own discharges; for in a large number of cases, and particularly in those of chronic wasting diseases, of inflammatory and febrile disorders in the typhoid stage, and of paralytic affections of the central nervous organs, there is a peculiar aptitude, especially under such circumstances, for the speedy production of bed-sores.

2. The maintenance of the patient's strength by the judicious administration of food is an essential element in the successful treatment of

disease. In most diseases, the tissues of the body disintegrate with unwonted rapidity, and emaciation and debility tend to supervene in a proportionate degree; and in most, this over-rapidity of disintegration is accompanied with loss of appetite, loathing of food, impairment of the nutritive functions, or some other condition, which renders it difficult or impossible to supply to the organism the alimentary matters necessary for its renovation and maintenance. If the obstacle lie in the patient's determination not to take food, as is the case with some lunatics, food must be administered by means of the stomach-pump; if it depend on some mechanical impediment in the œsophagus, stomach, or elsewhere, the food must be administered in such a form (for the most part fluid), and in such quantity, as will permit of its comparatively easy transmission through the constricted, compressed, or paralysed part. Failing such measures, operative procedure of some kind or other may under certain circumstances become advisable. If the patient's inability to take food depend upon irritability of the stomach, this condition must be remedied by suitable treatment, and all food administered meanwhile must be nutritious, unirritating, easy of digestion, and given in small quantities, and, if possible, frequently. Milk, barley-water, gruel, and the like are generally best adapted for such cases. Occasionally, however, small quantities of solid but well-comminuted food are preferable. If the patient be suffering from inflammation, fever, or other constitutional conditions, in which utter abeyance of all desire for food exists (associated as such abeyance often is with irritability of the stomach, and even difficulty of swallowing), it is generally advisable, in order to ensure the due administration of nutriment, to draw up, for the guidance of the nurses or other attendants, some scheme indicating how much food it is desirable to administer in the twenty-four hours, the intervals at which it should be supplied, and the quantity which should be given on each occasion. A teacupful, a wineglassful, or a tablespoonful of fluid nourishment may, according to the nature of the case, and the circumstances which arise, be directed to be administered every two hours, every hour, or every half-hour. The quantity given at one time should never (if it can be avoided) be so large as to cause sickness; and the frequency of administration must be regulated in some measure by the quantity which is given at each meal; but we must not be disheartened if we find (as is too often the case) that the patient is unable to take the whole amount of nourishment which we have determined upon as his minimum allowance. In cases of this kind nothing, as a rule, can be better than milk; and generally even those with whom it habitually disagrees can now take it with little difficulty; but it is often necessary to alternate its use with that of other nutritious fluids, such as gruel, barley-water, rice-water, arrowroot, corn-flour or biscuit-powder properly prepared with water or milk, or beef-tea, mutton-broth, chicken-broth or soup, or to replace it by them. Alcohol, in some form or other, is frequently necessary, and must then take its place in the rota. In all cases, whether of inflammation, fever, gastrointestinal affection, or mechanical obstacle to the entrance of food into

the stomach, if the amount administrable by the stomach be insufficient to maintain life, nutritious enemata must be systematically used; and, indeed, this mode of giving food may sometimes be employed temporarily with great benefit, to the total exclusion of that by the mouth, in cases of extreme irritability of the stomach. In many chronic diseases, such as pulmonary phthisis, the appetite often remains good, though perhaps variable and capricious, and hence it is a comparatively easy task to ensure the due administration of nourishment. The appetite is generally good, also, during convalescence from wasting disorders, and for the most part may be taken as an indication that the patient needs to be well fed. Although the rules above laid down are generally true, there are occasional exceptions to them; and moreover special diseases in some cases need special modifications of diet. A day or two of abstinence or of starvation is often beneficial, sometimes imperative; and, again, the importance is obvious of the avoidance of amylaceous matters by diabetic patients, and of excess of nitrogenous food by those who are suffering from Bright's disease. Persons frequently come under our care who are suffering not only from disease but from starvation, which may have commenced prior to the commencement of their disease or supervened upon it. Here especially the good effects of careful attention to the nutritive functions are often strikingly exemplified.

3. It has already been hinted, in the foregoing paragraph, that in many cases it is essential for the successful exhibition of nourishment that the stomach and bowels should first be rendered capable of retaining and acting upon the alimentary matters which are introduced into them. It is, in fact, always important, in the presence of disease, to maintain, or, as far as possible, to improve, the general welfare of the nutritive functions. To some, and indeed to no inconsiderable, extent this end may be attained, as we have pointed out, by the judicious administration of food. But in a large proportion of cases tonic medicines of various kinds are of extreme efficacy in this respect. It is needless to indicate the numerous cases in which iron, cinchona, cod-liver oil, and the like, act almost as specifics in the cure of disease. We wish, however, particularly to insist on their value in the treatment of many morbid conditions, in reference to which they do not possess obviously specific powers. Among these we may name the various forms of dropsy, and many other consequences or secondary phenomena of organic lesions of the heart, lungs, liver, kidneys, and other organs. In such cases it is generally necessary to adapt the form of tonic to the condition of the alimentary canal, or it may be to associate with it medicines which tend to soothe or stimulate the mucous membrane, or to act otherwise beneficially on it.

4. The notion of getting rid of the poisonous elements of disease, by eliminating them by the various excretories or other routes, is an old one. It happens unfortunately, however, that as a rule we have little or no power of thus discharging the proximate causes of disease. It is entirely beyond our competence to promote the separation from the system of the material factors of the various forms of inflammation, of the living

elements of malignant growths, or of the contagia of the infectious fevers. Neither can we, by the use of drugs taken into the stomach, cause the elimination or death of parasites imbedded in the organism, or even of such as infest the surface of the body. It is very different, however with regard to the chemical products of decomposition which are so abundant in many diseases, which so frequently tend in them to accumulate in the blood, and which so often by their presence therein cause toxæmic symptoms and thus add seriously to the dangers which the patient incurs. For this reason it is generally advisable to maintain, as far as possible, free action of the various secretory organs—the skin, kidneys, alimentary canal, and lungs. In febrile disorders not only is there usually a large over-production of urea and of matters related to urea, but the urine, by which alone they can be efficiently removed, is usually scanty. It is obviously desirable, therefore, in these cases, to promote the flow of urine; a result which may generally be best attained by allowing the patient to drink freely. In gout, a somewhat similar accumulation of effete matters, and especially of urate of soda, takes place in the blood, and consequently here again eliminative treatment is indicated. But not unfrequently poisonous matters accumulate in this fluid in consequence of structural disease of the organs by which they should be separated. In disease of the kidney, urea and other waste nitrogenous matters are retained in the blood, in disease of the liver the elements of bile, in disease of the lungs carbonic acid. Under these circumstances unconquerable obstacles frequently exist to the purification of the blood. Still, good may often be effected, if not by promoting the eliminative action of the implicated organ at any rate by encouraging the vicarious action of other organs. In renal disease much benefit is generally obtained by the regulated use of drastic purgatives, and by promoting profuse perspiration; and in liver disease with jaundice, by encouraging diuresis. Again, many substances, poisonous and other, which occasionally gain entrance into the organism, tend, like urea and other effete matters, to be thrown off: sometimes by the kidneys, sometimes by the lungs, sometimes into the parenchyma of certain organs. Their discharge may often be hastened by appropriate measures. It is an important statement that lead and mercury, which have an aptitude to be deposited in certain of the tissues, can be removed thence by means of iodide of potassium, with which they are said to unite in the organism, and in company with which then to escape with the urine. But eliminative treatment is by no means called for in all diseases; and, even where it is indicated, it must not be assumed that the emunctories must be powerfully stimulated into action, still less that we should act violently upon all at the same time. Here, as in other cases, we must be guided in our efforts by the nature of the case with which we have to deal, and by the phenomena which manifest themselves during its progress.

5. No inconsiderable part of the duties which a medical practitioner is called upon to perform consists in the treatment of the secondary phenomena or symptoms of disease: in relieving pain or uneasiness, in

giving sleep, in soothing irritability or anxiety of mind, in promoting or checking the action of certain organs, in removing or dissipating matters which, from their position or quantity, interfere with the due performance of functions that are important to life or health. And it is certain that, if we do not by such measures actually cure the primary disease, we often make life tolerable, we are often successful in prolonging life, and not unfrequently succeed in prolonging it until the disease, which would otherwise have carried the patient off, itself subsides, and by its subsidence leaves him convalescent. The importance of relieving pain in acute inflammation of the peritoneum or pleura, or in enteritis, and in various forms of neuralgia, is fully admitted by everyone. The necessity of giving sleep in traumatic delirium, in the wakefulness which sometimes precedes the outbreak of acute mania, and in many febrile and organic diseases, is equally recognised. The relief of spasmodic action of the voluntary muscles in tetanus, or of the involuntary muscles in spasmodic stricture of the urethra and various other tubular organs, is often a matter of urgent need; as also, on the other hand, is the stimulation of an inactive organ—of the heart under certain conditions, or of the flaccid uterus after parturition, when profuse hemorrhage is taking place. The last examples which we shall adduce are supplied by the removal, whether by tapping or by medicinal means, of dropsical accumulations in serous cavities, and the dissipation of effusions, tumours, or foreign bodies, which by their position compress or interfere with passages (such as the larynx, or bowels) the patency of which is necessary for the maintenance of life.

6. To obviate the tendency to death is to a great extent implied in the foregoing discussion. In a sense it is the principal aim of all medical treatment. The expression, however, is generally employed in reference to the duty which devolves upon us at the time when death appears to be imminent, and when the exact nature of the process by which death will be brought about becomes more or less clearly indicated. On a former page we have discussed the various modes of dying, and we must refer to what was there said for the special indications for treatment furnished in the several cases there enumerated.

SPECIAL PATHOLOGY

# SPECIAL PATHOLOGY

## CHAP. I.—SPECIFIC FEBRILE DISEASES

### I. INTRODUCTORY REMARKS IN REFERENCE MAINLY TO THE INFECTIOUS FEVERS

#### A. *Specific Origin and Spread of Epidemic and Endemic Diseases*

THE diseases, to which the following remarks are intended to be introductory, are for the most part linked together by the possession of certain striking characteristics. They originate severally in definite specific causes, they prevail endemically, or epidemically, and are in large proportion infectious or contagious.

1. *They originate in specific causes.*—To this subject we shall presently recur; meanwhile, the truth of the statement here made is proved by the fact that the several diseases of this group never pass the one into the other, or (notwithstanding that, within certain limits, they may present variations of character) lose their specific identity: that while malarious poison never causes small-pox, typhus, or scarlet fever, so the specific poison of either of these latter affections never gives origin to ague or to any other disease than that from which it was derived. Small-pox produces small-pox, typhus typhus, scarlatina scarlatina; and ague arises under special conditions which are productive of ague and of ague alone.

2. *They prevail endemically or epidemically.*—The term ‘endemic,’ as applied to disease, signifies the prevalence of disease among a people. For the most part, also, it implies its limitation within certain restricted areas, its dependence on local or localised causes, and a tendency to persist in the district which it affects. The term ‘epidemic,’ on the other hand, implies that the disease of which it is used falls as it were suddenly upon a people, and generally implies, further, that it spreads widely and rapidly, and that its prevalence is of limited duration. Goitre is the very type of an endemic disease, influenza perhaps the most characteristically epidemic of all epidemic diseases. It is important, however, to observe that epidemic diseases comport themselves in many different ways, and

that the epidemic and endemic conditions not unfrequently pass into one another. Influenza, and it may be added small-pox, scarlet fever, measles, and other like affections, when occurring for the first time in an unprotected community, diffuse themselves generally with marvellous rapidity. Typhus and relapsing fever, virulent though they be, limit their spread mainly to those who are under certain defective sanitary conditions. Cholera, though distinctly epidemic, diffuses itself mainly by irregularly scattered local outbreaks; a peculiarity still more markedly belonging to enteric fever and to diphtheria, which, moreover, are apt to persist in an endemic form, in the localities into which they have been introduced. Further, many affections, which are now more or less characteristically endemic, or epidemic within restricted areas, have been or are liable to become epidemic in the wider sense of the word, under certain ill-understood conditions; among these may be enumerated leprosy, syphilis, plague, and yellow fever.

3. *They are in large proportion infectious or contagious.*—It was formerly largely believed that epidemic disease was the result of the operation of some mysterious influence diffusing itself like a vapour over the surface of infected regions, involving equally the whole population, modifying the general health, tincturing the already prevalent diseases, and causing among those who were predisposed to it the specific epidemic attack. This view was once held with regard to syphilis itself: a disease now known, like hydrophobia and glanders, to be imparted only by direct inoculation. It is even now entertained by many in respect of influenza: a malady which is one of the most eminently contagious of maladies, and in this respect allied with small-pox, scarlet fever, and measles. That the origins of cholera and enteric fever were long enshrouded in mystery is not surprising; yet even in the case of these diseases there is now scarcely any difference of opinion as to their diffusion by means of specific contagia. And, indeed (though it has not yet been distinctly proved of every epidemic affection), the progress of pathological science leaves little room for doubt that all truly epidemic diseases are communicable directly or indirectly from the sick to the healthy, and that their spread is due solely to the operation of a specific virus which the former yield and the latter absorb. Endemic affections, on the other hand, are not necessarily infectious; and some (such as ague and goitre) seem clearly to originate in certain poisonous matters developed, or existing, in the soil of the localities which they affect.

4. *Behaviour of contagia within the organism.*—The virus or contagium of an infectious fever, having gained entrance into a susceptible body, apparently remains dormant in it for a time, which varies according to the nature of the fever, and is termed the period of *latency* or *incubation*. To this succeeds the period of *invasion*, during which the first symptoms of the disease manifest themselves. And on this soon supervenes, in its turn, the period during which the specific symptoms become declared. This, in the case of the exanthemata, is termed the *eruptive* period. In other varieties of infectious fevers, the period of invasion, and that

corresponding to the eruptive period, are for the most part indistinctly divided. In most cases, after the symptoms have endured for some definite time, they begin to abate: the period of *decline* or *defervescence* comes on. On this *convalescence* ensues, and the patient is presently restored to health.

In order to impart disease, the contagium must enter into the system. But the mode of its entrance, and the route by which it enters, differ in different cases. Some contagia (such as those of syphilis, glanders, hydrophobia, and vaccinia) can be introduced only by direct inoculation effected by placing them in substance on some delicate mucous surface, or by inserting them beneath the epidermis; some are carried by the atmosphere, are inhaled, and enter through the respiratory mucous membrane; some are introduced mainly with the food, and act primarily on the gastro-intestinal tract. Many of the diseases which are ordinarily conveyed by the air, or by food, have been found to be also communicable by inoculation; and it seems not improbable that, under favourable conditions, all such diseases might be thus imparted.

In some of the inoculable diseases (syphilis and small-pox to wit) a specific pimple gradually rises at the point of inoculation; specific affection of the lymphatic glands next above speedily ensues; and, at or about the time when these have attained their full development, febrile symptoms supervene, to be followed in a short time by the characteristic rash. In vaccinia the same sequence of events takes place, with the exception that the febrile symptoms are not succeeded by any specific cutaneous eruption. In these cases, the period of the development of the primary pimple or pock, and of the affection of the neighbouring lymphatic glands, corresponds accurately to the period of incubation of natural small-pox, or of other infectious fevers not acquired by inoculation. It is reasonable to believe that what occurs in these particular affections, during the period of incubation, occurs during the same period, with some modification of detail, in others: in other words, that specific local processes (followed by specific affection of the nearest lymphatic glands) take place in all of them during the period of incubation, and preliminary to the general diffusion of the poison, at the spot or spots at which the virus enters the organism. It is not improbable that the specific lesions of diphtheria, cholera, and enteric fever are to be regarded as the immediate consequences of the local action of the specific poisons of these diseases, and as corresponding therefore to the syphilitic chancre, or the primary pock of inoculated variola, and not to the eruption of the generalised disease.

The period of general diffusion follows; the infected lymphatic glands shed specific elements into the blood, with which they are distributed throughout the organism, to sow themselves in, or to infect, those parts of it which offer a suitable soil for their further development or growth. Various constitutional phenomena, due to the effects of the poison upon the blood and tissues, attend their diffusion; but, in addition to these, various specific lesions of particular parts ensue, which are more or less

characteristic for each form of disease. In many cases (the exanthemata, a rash appears upon the skin; in some the tonsils, in some the salivary glands, in some the respiratory tract, in some the alimentary canal, in some certain other internal organs, are mainly involved. It is obvious, from the above account, that the contagious matters of the contagious diseases must at some time or other be contained within the blood. The blood, indeed, in some cases and under certain conditions, is undoubtedly infectious. But, for the most part, this fluid rapidly purifies itself of the poisonous elements which enter it, discharging them mainly into those organs or tissues, or at those surfaces, which are the seats of the specific lesions of the diseases to which they belong, and which consequently become surcharged with infectious matter.

During the progress of a contagious disease, the contagium which gave it origin undergoes enormous development within the organism. An inconceivably minute quantity of the variolous poison, placed beneath the skin, results in the formation of a pock, which itself contains an infinitely larger amount of poison than was introduced in the first instance, and subsequently in the formation of thousands of pocks scattered over the general surface, each one of which is as fully charged with contagium as was the first. There can be no doubt that, in other diseases besides small-pox, this development of contagion goes on during the whole period of ingravescence: beginning at the seat of its introduction, continuing in the lymphatics and probably in the blood, but taking place with especial energy in the cutis in exanthematic diseases, and in connection generally with specific lesions.

In the majority of cases the poison, which is thus manufactured within the organism, is discharged from it in greater or less abundance, and serves to propagate the disease of which it is the specific cause. This discharge, which occurs mainly in connection with the seats of specific lesion, takes place at different periods in different diseases, and necessarily also from different surfaces. Thus, the contagia of cholera and enteric fever are discharged with the alvine evacuations; those of measles, whooping-cough, and influenza from the respiratory surface; that of scarlet fever probably from the throat and skin; that of hydrophobia with the saliva or oral mucus; that of glanders mainly with the nasal secretion; and that of syphilis with the discharges from its specific sores.

It is very remarkable that the majority of contagious fevers end in recovery: that the poisonous matters which they engender either die out or escape from the body by one or other of the routes which have been enumerated. This latter process has been compared to the discharge of urea, or other effete matters, by the emunctories. But it is obviously of quite a different character; for (to take small-pox again as an example) there is not simply a discharge from the diseased surface of matters which had accumulated in the blood, but there is an actual manufacture of poison going on at each spot of disease. There arises, further, a remarkable condition of the organism, by which its susceptibility of the specific poison is destroyed; for not only does the poison within it die out, but

the system refuses to re-absorb any of the abundant poison which it manufactures, and remains for many years, it may be for life, free from liability to become again affected.

5. *Behaviour of contagia externally to the body.*—There is a time during which contagia exist outside the body. How do they then comport themselves? It is clear that, in this respect, they present as important differences among themselves as they do in their influence over the body. The contagium of influenza is remarkable for its amazing diffusibility; that of typhus clings as it were around the patient and is readily destroyed by atmospheric dilution; that of scarlet fever remains dormant for months in articles of clothing; that of small-pox, or of vaccinia, may be preserved for years between two pieces of glass, or concreted upon an ivory point. But the most remarkable peculiarities are presented by the contagia of enteric fever and cholera. In both cases the specific poison is yielded by the bowel, and escapes with the fæces; and in both, probably, the poison is innocuous at the moment of escape, and only acquires virulent properties after the lapse of some time—in the case of cholera, after the lapse of four or five days. There can be little doubt, however (and the reasons for this statement will become more apparent subsequently), that under various conditions (of which only a few are understood) most contagia are apt to multiply or increase outside the body, and to present alternately phases of dormant or inert existence and of activity and virulence. Further, it is important to know that contagia, at any rate many of them, tend to cling to articles of clothing and furniture, to lurk in dirt and in neglected corners, and even to infect water, milk, and articles of food which have been exposed to their influence. The spread of enteric fever and scarlatina, and we believe also of diphtheria, has been traced in many instances to milk thus contaminated.

6. *Nature of contagia.*—Having briefly considered the dependence of epidemic diseases on specific contagia, and the modes by which these poisons enter the body, act upon it, and finally get discharged from it, together with some of their peculiarities of behaviour outside the organism, it remains to discuss the question of their nature. In reference to this subject, we must not lose sight of some of the important facts with regard to contagion which have been adduced: we must bear distinctly in mind, that the virus of one disease produces that disease only and never any other; that a virus received into the body multiplies indefinitely within it; that it leaves the body, not by the organs provided for the separation of effete matters, but by a process of efflorescence or multiplication, taking place in certain situations and modes, which are characteristic for each disease; and that externally to the body it comports itself in various manners, of which some (as in cholera and enteric fever) evidently imply progressive developmental changes. It seems impossible that these conditions can be fulfilled by any element, or any combination of elements, unendowed with life. No inorganic solid, still less any inorganic fluid or gas, no dead organic compound, could thus multiply itself either within or without the body, or thus affect the body in its progress through it.

It is impossible to conceive of a bubble of sulphuretted hydrogen, a drop of gin, a fragment of marble, or a grain of morphia, multiplying itself a thousandfold within the system, making for its discharge some special route, and leaving the system henceforth incapable of its further production. Nothing analogous to this has been shown to exist in the whole range of inorganic or organic chemistry. The facts, however, are all compatible with what we know of the development and behaviour of organised beings, and especially of such as are lowest in the scale of life. We know how, when the spores of fungi are deposited in a suitable soil, they grow and multiply and rapidly pervade it until they have exhausted it; how each fungus fructifies according to its specific character, and yields innumerable spores, which become widely diffused, and, though retaining their specific characters and their vitality under apparently the most adverse circumstances, remain dormant until the opportunity for their development offers itself. The above, however, is not the only argument in favour of the dependence of infectious fevers on living organisms. Others of greater value remain to be adduced. (a) We know that many diseases, among which may be mentioned *tinea tonsurans*, *tinea favosa*, *tinea versicolor*, scabies, and those in which *trichinæ* and *hydatids* are present, are actually due to the presence of animal or vegetable parasites; and that the behaviour of the living contagia in these cases manifests at least as great variety as does that of the virus of the infectious fevers. (b) The important experiments, first made by Chauveau, with regard to the infectious fluids of cow-pox, sheep-pox, and glanders, and since repeated in the case of cow-pox by Burdon Sanderson, show clearly that the contagious element is not uniformly diffused throughout these fluids, that it resides neither in the inflammatory corpuscles which they contain, nor in the dissolved constituents, but in certain minute protoplasmic particles or living bodies which, at the period of their chief infectiveness, they contain in great abundance. (c) Specific parasitic growths have actually been detected in connection with several of the diseases in question, under circumstances which leave little doubt that

FIG. 33.—SPIRILLA OF RELAPSING FEVER.  $\times 500$ .

they are the actual contagia, or specific elements, of these diseases. Some of the most important and conclusive observations relate to relapsing fever, and anthrax or the splenic fever of cattle. In relapsing fever, a form of bacterium named 'spirillum' was first detected in the blood by Obermeier in 1872. Spirilla are moving spiral filaments of extreme tenuity and measuring from  $\frac{1}{1500}$  to  $\frac{1}{500}$  inch in length. They are found in the blood in connection with the febrile paroxysms only; making their appearance in it shortly before the rise of

temperature commences, and disappearing from it just before the occurrence of the crisis. They vary in number from day to day during the persistence of fever, and disappear absolutely during the remission. The above facts have been confirmed by many subsequent observers, among

others by Heydenreich of St. Petersburg, who also shows experimentally that spirilla are very short-lived at febrile temperatures, and even at the normal temperature of the blood, and that there is good reason therefore to believe that their variable prevalence in the same attack is connected with the development and disappearance of successive generations. Experiments in regard to the inoculability of relapsing fever tend to substantiate the belief that spirilla constitute its contagious element; for the disease can be readily imparted by the blood of a patient in the febrile paroxysm, but not by that of the same patient during the apyrexial period, nor by his secretions at any time of his illness. In splenic fever, which is communicable only by direct contagion, and occasionally spreads in this way to man, peculiar organisms are always to be found in the blood, lymphatic glands, and spleen during the height of the disease. These are motionless, rod-like, bacteria from  $\frac{1}{1000}$  to  $\frac{1}{3000}$  inch in length, and have been named 'bacilli anthracis.' Koch has cultivated them ex-

FIG. 34.—BACILLI ANTHRACIS.  $\times 500$ .

a, rods; b, filaments in different stages obtained by cultivation; c, spores

ternally to the body, and finds that under suitable conditions they grow into branching filaments of considerable length; that the filaments, which are at first structureless and transparent, after a time become studded with small dots; that these gradually increase in size until they form oval spores, which presently, on the breaking down of the filaments, get detached. He also finds that the spores, like all spores, are bodies of robust vitality and comparatively indestructible; that under favourable circumstances they elongate into rods; and that under the continuance of such circumstances the rods themselves are capable of indefinite multiplication by fission. He further finds that mice are highly susceptible of the disease; and that while disease is not imparted to them by the bacillus in its filamentous form, it is readily given by either spores or rods. Further, the spores appear always to become rods in the organism, and the mycelial stage is never attained there; so that the rod-like form is the only one under which they seem to live parasitically. These observations have since been confirmed by other observers, among whom may be named Dr. Cossar Ewart and Dr. Greenfield.

The arguments in favour of the dependence of the specific contagious

diseases on living organisms, apart even from the remarkable series of observations which have just been adduced, seem almost conclusive. It might still, however, have remained a question whether these living organisms were animalcules, as some have supposed, vegetables as others believe, or particles of the living tissues of the patient, as Dr. Beale thinks, endowed with specific properties. But these recent discoveries go far to give a positive solution to this question, and at the same time to confirm the belief of those who maintain that the specific fevers (in other words, their specific causes) never originate *de novo*.

If contagia be lowly vegetable organisms, it is easy to understand how it is that they present so many characteristic differences of behaviour; how it is that they are infective at different periods of disease and under different circumstances; and how (if like the bacillus anthracis they pass through different phases of living, of which some are parasitic, some non-parasitic, some infective, some innocuous) they may from time to time pass an innocent or dormant existence externally to the body until favouring conditions bring them again to active infective life; how in fact (as in cholera, plague, typhus, and relapsing and enteric fevers) they may, from time to time and under special combinations of circumstances, appear to undergo spontaneous development.

Certain facts concerning splenic fever and ague have much interest and importance in relation to the subject adverted to in the above paragraph. Pasteur has demonstrated that the bacillus anthracis still flourishes in pits in which animals dead of splenic fever have been buried, even for ten years, and still retains all its virulence. On a subsequent page it is shown that ague occasionally reappears, apparently in consequence of extensive recent upheavals of the soil, in places which have long been free from it; and attention is drawn to the investigations of Klebs and Tommasi-Crudeli, which serve to prove that this disease is caused by a vegetable organism, the bacillus malariae, which flourishes in the soil of malarious districts. If these observations be true, we have in them a sufficient explanation of the occasional apparently spontaneous origin of ague and splenic fever, which is entirely compatible with the belief in their specific nature which we have endeavoured to inculcate.

7. *Attenuation or mitigation of contagia.*—In June 1880 Dr. Greenfield published the results of some experimental inquiries which seemed to show that by cultivation the bacillus anthracis can be so mitigated in virulence as on inoculation to produce a mild and non-fatal form of splenic fever, which is nevertheless protective against future attacks of the disease. About the same time Pasteur was proving experimentally that the virus of a very fatal infectious disease of fowls, known as ‘chicken-cholera,’ can be attenuated with like results; and his researches were made public two or three months later. Since then he has extended his investigations to splenic fever. And in August 1881 he gave a collective account of his experiments and results in a remarkable address delivered before the International Medical Congress. The following is a brief abstract of his more important statements.

The virus of chicken-cholera is an extremely minute micro-organism, for the most part resembling the figure 8, which, like the yeast plant in beer, multiplies by fission or gemmation, and never produces spores. At a temperature of  $77^{\circ}$  to  $95^{\circ}$  this may be cultivated in chicken broth; and the cultivation may be carried on indefinitely by successively impregnating fresh portions of broth with minute particles of fluid from the portions in which cultivation is already in progress. Now if this cultivation take place in vessels hermetically sealed, every cultivation, no matter how far removed from the original stock, retains the full virulence of the primary virus. But Pasteur discovered that if the process be conducted in vessels closed with stoppers of cotton wool, which, while preventing the entrance of organisms from without, give free access to the oxygen of the atmosphere, and sufficient time (a fortnight or more) be allowed between successive cultivation-experiments, the cultivation-products grow less and less virulent; until at length, without change of anatomical character, they become absolutely innocuous. He discovered also that at certain stages of attenuation, before complete innocuousness is reached, the cultivation-fluid on inoculation causes, like vaccine-lymph, local mischief with only slight constitutional disturbance—a trivial malady, always followed by speedy restoration to health; and that this attenuated attack of chicken-cholera is protective (at any rate for a year) against future attacks of the disease.

The virus of splenic fever, as we have shown, forms, when cultivated, jointed filaments, within which spores are developed. Now spores, like the seeds of higher plants, produce offspring endowed with all the fundamental properties of the parent organisms; while by gemmation or fission (as by buds or cuttings) accidental or acquired peculiarities are also perpetuated. It might almost have been assumed therefore that so long as cultivation produced spore-bearing filaments, its products would retain all the virulence of the original virus. And so Pasteur found. He discovered, however, that by performing his cultivation-experiments at a temperature of  $107.5^{\circ}$  to  $109.5^{\circ}$  (or just a little below the temperature at which cultivation becomes impossible), a filamentous growth results wholly free from spores; and that on repeated cultivation this form of the bacillus presents all the dynamic peculiarities manifested under similar conditions by the virus of chicken-cholera. By this attenuated poison he imparted to susceptible cattle a mild form of splenic fever unattended with danger to life, which has proved perfectly protective against subsequent inoculations of the disease in its most virulent form. This method of protection has already been practised in France on a large scale and with entire success. Pasteur believes that the attenuation of the poison is due mainly to the influence of oxygen.

It is scarcely necessary to draw attention to the important bearing these investigations appear to have on the relation of cow-pox to small-pox, and to the hope which they raise that the contagia of other infectious diseases may also prove capable of mitigation.

8. *Septicæmia*.—In connection with the subject just discussed, as well

as on account of their intrinsic importance, it seems desirable to call attention, however briefly, to the observations made in recent years in regard to the influence of septic organisms or bacteria in the production of disease. It seems now to be well ascertained that septic bacteria, or their invisible spores, are largely diffused throughout nature, but mainly in connection with water and watery vapour; that they rapidly attack all organic infusions and all dead or dying animal or vegetable matters which are not specially protected from them; and that they are in fact the essential agents in all putrefactive processes. It has also been ascertained that these organisms tend to breed in our bowels, and on those other mucous surfaces to which the air has ready access, and especially to attack external wounds or ulcers. And it has further been ascertained, beyond the possibility of doubt, that when such parts become foul and unhealthy, and their secretions fetid, these conditions are always associated with an enormous development of septic bacteria, which are then found mainly in the diseased tissues, but also in the adjoining lymphatics, and generally to some extent in the circulating blood. It was a natural inference, that under these circumstances the bacteria were not only important (if not essential) agents in the local unhealthy processes, but largely (if not solely) instrumental in causing the constitutional disturbance which was associated with them, and in the propagation of unhealthy inflammation from patient to patient—that they were, in fact, contagia in the sense in which we have hitherto employed that word. Further investigations have partly confirmed, partly corrected, this inference. They have confirmed it, by demonstrating that the development of bacteria is essential to the production of the local putrefactive changes and general febrile symptoms, and to the communicability of the morbid process. They have corrected it, by proving that while under some conditions bacteria diffuse themselves throughout the organism and multiply in it, and behave in all respects like true contagia, under other conditions their growth and increase are purely local, and whatever injurious influence they exert over the system is due, not to their direct action, but to an unorganised poison which they generate, and which becomes absorbed. Whether this difference in behaviour of micro-organisms which seem to be identical be due to accidental conditions in themselves or in the soil in which they grow, or to the fact that they comprise various species, having different properties, which thus reveal themselves, is a question difficult of solution. The latter is the explanation to which we incline.

Sanderson's investigations relate mainly to those cases in which the local growth of bacteria tends to produce specific symptoms by throwing into the system, either continuously or from time to time, a poison which is of local manufacture, which has no power of self-multiplication, and which is incapable, therefore, of imparting disease to others by simple inoculation. This septic poison is soluble, and can be obtained in solution, entirely free from bacterial or other organisms, and from putrefactive taint or tendency. It is of extreme virulence (its effects

being proportionate to its dose), and has exactly the same effect on the system as the material containing bacteria from which it is obtained. When injected into the tissues of the dog, it gives rise to the following phenomena: the animal first shudders and then moves about restlessly from place to place; its gait becomes unsteady, and in a short time it staggers, and falls on its side; in the meanwhile, vomiting and violent tenesmus, followed by the discharge first of fæcal and subsequently of mucous dejecta, take place; and then, if death do not ensue, the symptoms quickly subside, and the animal recovers its normal appetite and liveliness. During the attack the temperature rises gradually to about a couple of degrees above the normal, and then, whether recovery or death ensues, gradually falls. Immediately before death the fall is rapid. In fatal cases, small extravasations of blood are found beneath the endocardium (mainly of the left ventricle), pericardium, and pleuræ, and the abdominal organs are generally congested; but the mucous membrane of the stomach and small intestines is hyperæmic to an extreme degree, and the spleen large and infiltrated with blood. The blood is darker than natural, owing mainly to the fact that the red corpuscles are partially dissolved, and their colouring matter is diffused to some extent through the plasma. Extreme anæmia is generally observed after recovery.

The infective variety of septicæmia (that, namely, in which the introduction of small quantities of septic organisms into the blood is followed by

FIG. 35.—VEIN OF THE DIAPHRAGM OF A SEPTICÆMIC MOUSE.  $\times 700$  (Koch).

- a. Nuclei of the vascular wall.
- b. Septicæmic bacilli.
- c. White corpuscles transformed into masses of bacilli.
- d. Capillaries opening into the vein.

the rapid increase and diffusion of such organisms throughout the system, with the development of characteristic symptoms, and by communicability of the same disease by inoculation to other individuals) has been experimentally investigated by Koch and others in mice and rabbits. The symptoms observed during life and the appearances found after death are

much the same in this affection as in the last, with the exception that in this case numberless bacteria are found in the blood and tissues, and that the disease is much more fatal.

The term *septic poisoning* may be conveniently applied to the former variety of septicæmia, and that of *septic infection* to the latter.

The relations of human septicæmia and pyæmia to the diseases above described are extremely interesting, but not absolutely clear. There can be no doubt that they, as well as the affections experimentally imparted to the lower animals, are due to bacterial influence. It seems probable that the constitutional symptoms attending local unhealthy inflammations, and which are by no means generally fatal, are due to septic poisoning. There is little reason to doubt that deaths, attributed to septicæmia or pyæmia after childbirth, and under other circumstances, and in which none of the characteristic lesions of true pyæmia are found after death, are cases of septic infection. And as regards pyæmia itself (in which we find vessels obstructed by emboli or clots, and local foci of disease more or less widely distributed, and in which all these lesions are centres of abundant bacterial development), it may be admitted that, if not identical in etiology, it has, at any rate, a very close affinity with true septic infection.

In the foregoing discussion we have dwelt on the distinction between the bacteria of septic poisoning and the true contagia—that in the former case the organisms undergo development in some limited area where they evolve a material, unliving poison, which is thrown into the system and thus acts injuriously upon it, while in the latter case the organisms themselves enter the system, undergo development within it, and thus produce their characteristic effects. But, while admitting the reality of the distinction, is it, we may ask, a fundamental one? It can scarcely be supposed that the true contagia act otherwise on the body than by some poison, which they yield or produce; and if this be the case it can only be a matter of subordinate scientific importance, whether the contagia which evolve poison multiply within the blood as in relapsing fever, in the skin (mainly) as in small-pox, or in ready-formed ulcerated surfaces as in septic poisoning. These remarks not merely have reference to the organisms of septicæmia on the one hand and the contagia of the exanthemata and continued fevers on the other, but they bear upon the question of the nature of the contagious elements in diphtheria, enteric fever, and some few other diseases in which lowly organisms (micrococci or bacteria) have been detected in connection with the characteristic local lesions, but in which the relations between organism and disease have not yet been satisfactorily determined.

#### B. *General Rules to be observed in the Management of Epidemic or Contagious Diseases*

We can, as a rule, do little or nothing medicinally for the direct cure of the infectious fevers. So far as the patient is concerned, we can only

treat symptoms as they arise, support his strength by suitable nourishment, promote the action of his excretory organs, and take precautions against the supervention of complications. It is, however, a most important duty of the medical man to prevent their spread. The measures to be adopted for this end will differ to some extent, according to the character of the disease he has to deal with, and according to the properties and peculiarities of the contagium on which it depends. The following general rules, partly derived from 'Suggestions by the Society of Medical Officers of Health,' partly from other sources, may be laid down as generally applicable :—

1. The patient should be at once separated, as efficiently as circumstances permit, from the other inmates of the house, and if possible placed in a top room, and have that floor devoted to him and his attendant.

2. All bed-curtains and other hangings, and carpets, and all articles of dress and the like in wardrobes and cupboards, and all unnecessary articles of furniture, should be removed.

3. The room should be well ventilated; windows should be kept partly open, communication with the chimney free, and, if the weather or size of the room permit, the fire burning. The floor should be sprinkled daily with disinfectant fluid and cleansed.

4. The door should be kept closed, and a sheet kept wet with a solution of carbolic acid, chloride of lime, or Condy's fluid, hung outside it so as to cover every crevice.

5. Everything that passes from the patient (spit, vomit, urine, fæces) should be received into vessels containing either of the above solutions, and an additional quantity of solution should be added to the vessel before removing it from the room and emptying it into the closet. All superabundant food or drink, and all scraps, should be similarly treated, and under no circumstances partaken of by other persons.

6. Pieces of rag should be used for wiping discharges from the nose or mouth, and burnt immediately after use.

7. All cups, glasses, spoons, and such-like articles used in the sick-room should be placed in some disinfectant solution before leaving it, and subsequently washed in hot water.

8. All bed and body linen after use should at once, and before leaving the room, be put into a disinfectant solution; and after remaining in this, for at least an hour, be boiled in water.

9. The patient's person and bed should be kept scrupulously clean; and when, during the progress of the disease, scales or crusts form upon the skin, their diffusion should be prevented by smearing the surface daily with oil.

10. Nurses in attendance should, if possible, be such as have already had their patient's disease; their dresses should be of cotton or some other washable material; they should keep their hands clean, using carbolic acid soap, or adding Condy's fluid to the water in which they wash, and should as far as possible avoid inhaling the patient's breath, or other emanations from his person or discharges. They should remain with the

patient ; or, if compelled to leave the room, leave it under proper precautions, and under no circumstances mix with other members of the household.

11. Visitors should not be allowed ; or, if allowed, should conform, as closely as circumstances permit, to the conditions required of the ordinary attendant.

12. The medical attendant should remain no longer than necessary in the sick-room, and expose himself as little as possible to contamination ; should wash his hands before leaving ; hold as little subsequent communication as possible with the inmates of the house ; and never go direct, or without proper precautions, from the infectious to other patients.

13. The patient must not be allowed to mix with the rest of his family until all peeling of the skin has ceased, or until all specific phenomena of disease have disappeared, and until he has been well purified by the use of warm baths and carbolic acid soap or Condyl's fluid. Clothes used during the time of illness, or in any way exposed to infection, must not be worn again until they have been properly disinfected.

14. When the sickness has terminated, the sick-room and its contents should be disinfected and cleansed. This should be done in the following manner :—Spread out, and hang upon lines, all articles of clothing or bedding ; well close the fireplace, windows, and all openings ; then take from a quarter to half a pound of brimstone, broken into small pieces ; put it into an iron dish, supported over a pail of water, and set fire to it by putting some live coals upon it ; then close the door, stopping all crevices, and allow the room to remain shut up for twenty-four hours. At the end of this time the room should be freely ventilated by opening doors, windows, and fireplace ; the ceiling should be whitewashed, the paper stripped from the walls and burnt, and the furniture and all wood and painted work washed with soap and water containing a little chloride of lime. Beds, mattresses, and other articles which cannot well be washed should, if possible, be submitted to a heat of from 210 to 250 degrees, for two hours or more, in a disinfecting chamber.

15. The house in which the patient, suffering from infectious disease, resides, should, during his illness, be well ventilated and kept very clean ; all sinks and water-closets should be in good order, and have solution of sulphate of iron, carbolic acid, or chloride of lime poured into them daily ; dustbins should be regularly emptied, all offensive accumulations removed or disinfected by the free use of chloride of lime, and all water-butts and cisterns kept clean and well covered. Indeed, the greatest possible care should be taken to prevent any contamination of drinking-water.

For the purposes of direct disinfection, many different substances may be employed. The following are among the most commonly useful :—Sulphate of iron, one pound to the gallon of water ; chloride of lime, one pound to the gallon ; carbolic acid (No. 4), a quarter of a pint to the gallon ; Condyl's red fluid diluted with fifty times its bulk of water ; the green fluid with thirty times its bulk of water. Chloride of lime, carbolic acid, and Condyl's fluid are, on the whole, preferable for disinfection in connection

with the infectious fevers. For the disinfection of linen and other wearing apparel, chloride of lime should be avoided, on account of its corrosive quality. Solution of carbolic acid, or of Condy's fluid, is preferable.

---

## II. INFLUENZA (*Epidemic Catarrh*)

*Definition.*—A contagious catarrhal affection of the respiratory tract, of short duration, but attended with much prostration, and occurring, for the most part, in widespread epidemics.

*Causation and history.*—Influenza is one of the most mysterious, and at the same time one of the most interesting, diseases with which we are acquainted. The obscurity of its origin; the swiftness with which it spreads throughout a district into which it has been introduced, and passes from one city to another city, from one country to another country, thus involving entire continents within very brief limits of time; the shortness of its stay in any locality, which rarely exceeds six weeks or two months; the suddenness and completeness of its disappearance; and the irregularity of its epidemic visitations, all combine to render it the most typical of all epidemic diseases. Its origin and diffusion, therefore, have not unnaturally been sought for in some occult telluric, atmospheric, or electrical condition, some widespread morbid influence external to, and independent of, the frames which it affects. On the other hand, experience has shown that its prevalence is altogether independent of climate and season, and has no relation to defective drainage or other local sources of sanitary evils. But its conveyance has frequently been traced from locality to locality by the direct agency of those who are suffering from it, and its diffusion in fresh localities from these infective immigrants as centres. It is certain, therefore, that it is infectious in a very high degree, and that it may be imparted by a contagium, which like other contagia, is specific, multiplies indefinitely in the body into which it has gained access, and is thence evolved in marvellous abundance. Under these circumstances it seems most philosophical, at all events most consonant with the present state of our knowledge, to reject the vague theories first adverted to, and to assume that the contagious influence, which certainly causes it to spread in large numbers of cases from man to man, affords the true explanation of its epidemic diffusion. The virus is doubtless given off with the breath. The disease has never been imparted by inoculation; its attacks are in no degree determined by age or sex; and it is quite uncertain whether, or to what degree, one attack is protective for the future. It has been held by some that epidemics of influenza have a tendency to precede, or to follow, or to be associated with, other epidemic diseases, such as cholera. This relation is doubtless accidental.

*Symptoms and progress.*—The duration of the latent period of influenza has not been accurately ascertained. According to Dr. Squire it is very short, namely, three or four days, or at the outside a week. Its invasion

is for the most part sudden, and marked by elevation of temperature ; chills, especially along the spine, sometimes amounting to rigors, and alternating with flushes of heat ; pain, uneasiness, or a sensation of burning in the back and limbs ; and sometimes vomiting. With these phenomena are associated, occasionally from the beginning, but more commonly after the lapse of some hours, severe catarrhal symptoms, indicated by dryness, redness, and swelling of the mucous membrane of the nose, sneezing, and, in consequence of involvement of the frontal sinuses, intense frontal headache ; affection of the conjunctivæ, and pain in the eyeballs ; inflammation of the fauces, larynx, trachea, and bronchial tubes to their smallest ramifications, with soreness of throat, hoarseness, constant hacking, often croupy, cough, rapidity and difficulty of breathing, and a sense of tightness or constriction of the chest. Generally at this time the skin is dry, the tongue covered with a moist fur, the appetite lost, the pulse quickened and moderately full, the bowels confined, and the urine febrile ; but, above all, there is extreme prostration, with muscular weakness, depression of spirits, and præcordial oppression. In the subsequent progress of the disease, general prostration and inflammation of the bronchial tubes constitute its most striking features. Now the heat of skin probably subsides somewhat, but the patient is still apt to have alternate chills and flushes ; the fever assumes a remittent character ; perspirations, which are sometimes very copious, break out ; not unfrequently sudamina appear, and occasionally an herpetic eruption about the lips ; the mucous membrane of the nose and respiratory passages secretes a thin, colourless mucus, which before long assumes a mucopurulent character ; the soreness of the throat and hoarseness probably continue ; the difficulty of breathing and the cough increase ; and on auscultation the breath sounds are found to be feeble, or masked by sibilant and sonorous rhonchi and sub-crepitation ; the face gets congested or livid ; the pulse increases in rapidity, and loses fulness and strength ; the tongue becomes more thickly coated, except perhaps at the tip and edges, and maybe dry and brown ; the sickness possibly continues, and diarrhœa may come on ; debility grows extreme, and muscular tremors and sub-sultus may appear ; the intelligence becomes markedly dull and impaired, and delirium sometimes supervenes. Epistaxis is of common occurrence, and otitis and jaundice are neither of them unfrequent.

In mild cases, the disease is at its height on the second or third day, and then declines gradually ; but in more severe cases (cases in which there is much pulmonary affection) convalescence does not commence until as late as the tenth or twelfth day. The patient is always much reduced in strength at this time, and convalescence is protracted in consequence, partly of persistent debility, partly of the continuance of catarrhal affections, or of a proclivity to catch cold.

The most important of the complications of influenza are those arising out of the characteristic lesions of the air-passages, namely, laryngeal inflammation, bronchitis (especially bronchitis of the smaller tubes), and lobular and lobar pneumonia, often associated with pleurisy. These affec-

tions creep on insidiously during the progress of the case, and reveal themselves only by aggravation of the ordinary symptoms, or by the blending of their proper symptoms with those due to the influenza itself. Gastro-intestinal complications also are described, and occur; but there is no doubt that the accidental concurrence (which is so common) of influenza with other diseases explains a large proportion of the cases in which it is found associated with these gastro-intestinal and other less frequent complications.

Single cases of influenza may readily be confounded with severe catarrhal affections of the nose, throat, and bronchial tubes. But the high fever, extreme prostration, and short duration of the graver symptoms are, all, important characteristics pointing to the specific nature of the disease. If to these peculiarities be added the fact of epidemic prevalence, mistake is no longer possible.

The percentage of deaths from influenza is very small, and indeed the uncomplicated disease is rarely fatal. Still, it attacks so large a proportion of a population (in some cases between a quarter and a half of the total number) that that small percentage does very largely augment the mortality rate. Indeed the prevalence of influenza has been found to swell the death-rate much more than the prevalence of cholera. The disease is chiefly fatal among the old, and such as are already suffering from pulmonary or cardiac affections.

*Morbid anatomy.*—There is nothing distinctive in the morbid anatomy of influenza. Patients die chiefly of pulmonary mischief, and the evidences of this may be detected in the form of inflammation of the bronchial membrane, secretion into the tubes, emphysema or collapse of lung-tissue, or both, or pneumonia, combined or not with pleurisy.

*Treatment.*—In treating influenza, it is important to adopt the hygienic measures which are generally useful in the treatment of infectious febrile affections. Medicinal treatment is not generally very efficacious. Small doses of nitre, alone, or combined with a few drops of laudanum, have been highly recommended. But probably nothing is better than a few drops of ipecacuanha wine combined with a little laudanum, or ammonia associated with solution of acetate of ammonia, administered every two or three hours. If the bowels are confined, they may be moved either by mild aperients or by enemata. The inhalation of steam may relieve the laryngeal and bronchial affection, as also may the diffusion of moisture through the atmosphere of the room. The removal of blood, even by leeches, is rarely admissible; still, in cases in which the congestion of the lungs is extreme, and death by asphyxia impending, they may be justifiably employed. Blisters again are of doubtful efficacy. Flannel or cotton wool, bran-poultices or hot fomentations to the chest, on the other hand, are often beneficial, as also are mustard plaisters. But little food will probably be taken, or needed, during the earlier days of the disease, and such as is swallowed should consist mainly or exclusively of milk, and the various farinacea, suspended or dissolved in milk or water. Thirst may be relieved by these means, or

by the administration of water, tea, lemonade, soda-water, or other such drinks. Owing to the remarkable prostration which generally is present, stimulants are for the most part soon required. The nature of the stimulants to be employed must depend on circumstances. When the patient begins to amend, tonics are indicated, and the diet must be gradually modified, until it combines the ordinary proportions of solid and fluid, and of animal and vegetable matters which constitute the diet of healthy persons. The presence of complications will necessarily, in many cases, make some modification of treatment desirable. It need only be said, however, in reference to this point, that, as in the uncomplicated disease, so here, depletory measures are generally attended with risk, and rarely called for.

---

### III. HOOPING COUGH (*Pertussis*)

*Definition.*—An infectious disorder, for the most part of long duration, characterised by inflammation of the respiratory tract and a peculiar paroxysmal cough.

*Causation.*—Hooping cough is met with both sporadically and in an epidemic form, mainly attacking children, but not altogether sparing adults or persons of advanced age. It is said to be more common in spring and autumn than in other seasons; it is probably not more common at these times, but attended then with a specially high mortality. Neither climate, nor other hygienic conditions, have any notable influence in promoting its spread; but epidemics of it are often associated with epidemics of scarlet fever or measles, and it is held by many that there is some kind of mysterious relation or attraction between them. It is contagious in a very high degree, especially during the earlier period of the disease, and before the whoop is established. Its contagion is given off with the breath, and conveyed mainly by the atmosphere; but it is readily carried by clothes, and preserved in fomites. One attack confers almost complete immunity against subsequent attacks.

*Symptoms and progress.*—As in all similar diseases, a period of latency intervenes between the inception of the virus and the occurrence of symptoms. The duration of this period has not been accurately ascertained. It was exactly a fortnight in some cases which we had the opportunity of investigating in reference to this point.

The invasion of hooping cough closely resembles that of an ordinary catarrh, and is often undistinguishable from it. There is more or less fever, with irritability or inflammation of the mucous membrane of the respiratory tract, and frequent cough, attended with much tickling in the throat and some expectoration of mucus. Some sonorous and sibilant rhonchus may be detected on listening to the chest, but in other respects the respiratory sounds are healthy. There may be injection of the conjunctivæ, photophobia, and nasal catarrh, with sneezing. The main points in which the disease differs thus early from ordinary catarrh are: that

the fever is commonly higher ; that the cough is much more troublesome, sometimes occurring incessantly night and day, several times in the minute ; and that these symptoms are all much more persistent, often lasting for a week or fortnight without undergoing any change.

About the end of this time the symptoms become modified ; the fever abates, and probably soon disappears, and gradually the irritative cough of the period of invasion subsides, to be replaced by the peculiar paroxysmal cough which characterises the disease. Single paroxysms of this cough may be almost exactly simulated, especially in children, by the effects of the application of pepper or other irritants to the laryngeal mucous membrane. But in its best-developed form, and by its recurrence, it is quite pathognomonic. The paroxysm is preceded by tickling in the throat, and perhaps pain beneath the sternum, and at the same time a little rhonchus is probably audible on applying the ear to the chest. The child seems to know what is impending, becomes quiet and anxious, and for a short time seems to struggle against it. If lying down, it rises to the sitting or standing posture, and when up, clutches any firm object which is near, or rushes to its nurse or mother. The actual attack usually begins with a deep inspiration. This is at once followed by a rapid succession of short coughs, with no intervening inspirations, which, gradually becoming feebler and feebler, are continued until the cavity of the chest is contracted to the utmost, the veins of the head and neck are turgid, the face congested and livid, the eyes watery and starting from their sockets, and the whole surface bathed in sweat, and asphyxia seems imminent. Then succeeds a long, whistling, crowing, or whooping inspiration, which is prolonged until the chest is once more distended with air. But the patient is not yet relieved ; for the cough immediately recurs, and may be repeated two or three times in immediate succession, until the child is utterly exhausted. During the paroxysm, which often lasts for two or three minutes, and more especially at its close, a considerable quantity of viscid transparent mucus is discharged, and very often the contents of the stomach are vomited. In the attack the child may faint or become insensible ; the urine and even the *fæces* may be voided ; punctiform extravasations of blood may occur beneath the conjunctivæ, and in the skin of the eyelids and other parts of the face ; and there may be hemorrhage from the nose, and even from the air-passages and ears. The *membranæ tympani* have been ruptured. The attack does not invariably begin in the manner above described, for often the paroxysmal cough comes on without any preceding inspiration, and occasionally complete spasmodic closure of the glottis, followed perhaps by insensibility, replaces it altogether. After the paroxysm is over, the child remains more or less exhausted for a time, but for the most part soon resumes his amusements, and appears to have little or nothing the matter with him. The paroxysms recur at irregular intervals, and vary in number from twenty to two hundred (according to the severity of the case) in the course of the day and night, but are almost always more numerous, as well as more severe, at night time. In the interparoxysmal period, auscultation of the chest reveals only slight indi-

cations of catarrh, but when the patient is making the crowing inspiration no breath-sounds whatever are audible within the chest. Ulceration of the frænum linguæ is often observed in children affected with whooping cough, and has had some importance attached to it. It seems to be due to injury by the lower incisors during the acts of coughing.

After the above symptoms have lasted with little change for several weeks (usually from three or four to eight or ten), the period of convalescence commences. This is of very various duration, and is especially apt to be prolonged if the weather be inclement, if the patient be neglected, or if complications have supervened. During its continuance, the attacks of cough gradually decrease in number and severity and lose their paroxysmal character; the expectoration becomes thicker and opaque, and then ceases; and the patient more or less rapidly regains health and strength.

Attacks of whooping cough vary much in severity and duration; and, just as scarlet fever or measles may occur without the development of its characteristic rash, so whooping cough may pass through all its stages and yet its cough never be attended with the characteristic whoop. This is especially the case when the disease is of exceptional mildness, or when it affects the adult. Trousseau records a case in which an attack lasted three days only. Its entire duration may certainly be as short as a week or two, but much more frequently ranges between six and twelve weeks. Occasionally the disease does not wholly disappear for six, or even twelve months. If, in the fully developed disease, the paroxysms of cough do not exceed twenty in the four-and-twenty hours, the case may be regarded as a mild one. If they exceed forty or fifty, the case is certainly severe, and the child probably is ill and feverish, and has signs of pulmonary congestion or bronchitis in the intervals between them. If they are still more numerous, the danger of complications, and to life, is serious. Whooping cough (although one of the most common causes of death in children) is rarely fatal in the absence of complications. These are apt to come on in the second period of the disease, especially in cases of great severity. They are mainly vomiting, bronchial inflammation, pulmonary collapse, lobular pneumonia, and emphysema, together with epileptiform convulsions and other forms of head-mischief. Vomiting chiefly attends the paroxysms of cough, and, if these be frequent, innutrition, emaciation, and debility will necessarily result. The pulmonary complications reveal themselves by difficulty of breathing, lividity of face, crepitation and sibilant rhonchus (without any necessary dulness on percussion of the chest), increased frequency of pulse, and rapid impairment of strength. The emphysema of the lungs, which is the result of laceration of the air-cells, is in children often interlobular, and occasionally spreads through the roots of the lungs to the connective tissue of the neck, face, and chest. Convulsions occur, chiefly in infants who are teething, and may be either ordinary attacks of eclampsia, or attacks resembling those of laryngismus stridulus, in which respiration is arrested by spasmodic closure of the glottis, and insensibility supervenes, attended with convulsive movements

of the muscles of the face and eyes. These complications are no doubt serious, and the latter especially may be suddenly fatal, yet the great majority of children who experience them recover perfectly. Edward Smith has shown that hooping cough is the most fatal of all diseases of children under one year of age, that sixty-eight per cent. of all the deaths from it occur under two years of age, and only six per cent. above the age of five years.

*Morbid anatomy.*—The lesions observed after death from hooping cough are always those of its complications, namely, congestion of the mucous membrane of the larynx and other air-passages with secretion into the bronchial tubes, collapse of lung-tissue in patches, lobular pneumonia, emphysema, and in children interlobular emphysema. Post-mortem examination, indeed, throws no light whatever on the nature of the disease. Congestions of the medulla oblongata, and of the pneumogastric nerves, which have been described as occurring in hooping cough, are probably purely accidental conditions, if not the result of mere post-mortem changes. So, again, enlargement of the bronchial glands, which has often been observed, has no necessary connection with it.<sup>v</sup> It has been much discussed whether the disease is essentially nervous, or a mere inflammatory condition of the respiratory mucous membrane. It seems probable, however, that it is not exactly either one or the other; but that, like other infectious fevers, it is the result of a virus, which affects more or less the whole system, but has a special tendency to involve the respiratory mucous membrane, producing in it a slight but specific inflammatory change, to the effects of which on the peripheral ends of the pneumogastric nerves the cough, with its peculiar characteristics, is due. This view is confirmed by the fact that it is evidently from the implicated mucous surface that the contagium of the disease is chiefly, if not exclusively, emitted.

*Treatment.*—As is the case with all diseases of uncertain duration and of intractability, many specifics have been vaunted for the successful treatment of hooping cough. Among the more important of these are hydrocyanic acid and belladonna. With respect to the latter remedy, Trousseau strongly urges that it should be given in one dose daily, and that in the morning on an empty stomach; and that, if an increase be necessary, it should be by augmentation of the morning's dose. For infants under four he recommends, to begin with, a pill made with  $\frac{1}{10}$  gr. of the extract and  $\frac{1}{10}$  gr. of the powdered leaves, or  $\frac{1}{200}$  gr. of the neutral sulphate of atropia. Large doses of belladonna are borne by young children, and from five to ten or even fifteen minims of the tincture may be administered to them several times a day. If hydrocyanic acid be preferred, from one to two minims of the dilute preparation may (according to Dr. Roe) be given to young children every three or four hours. Strychnia, hyoscyamus, conium, arsenic, iron, bromide of potassium, and bromide of ammonium have also been strongly recommended, as also have alum, tannin, and the mineral acids. But it is almost certain that no drug has any direct influence over the course of the disease, and that

hence our efforts must be directed to the relief of distressing symptoms, to the prevention of complications, and to the maintenance of the patient's strength. To these ends it is important that he be kept to his room, which, though well ventilated, should be maintained of uniform temperature; that, if not confined to bed, he be clothed in flannel; and generally that he be not exposed to draughts, or conditions liable to cause pulmonary inflammation. For medicine there is probably nothing better than a combination of a few drops of ipecacuanha wine with a minute proportion of laudanum or belladonna, to be administered every two, three, or four hours. Counter-irritants are sometimes useful; and the application of a strong solution of nitrate of silver to the larynx has been much recommended, especially by Bouchut and Eben Watson. A few whiffs of chloroform often relieve the paroxysms of cough. The patient's diet must be regulated according to circumstances, but generally it should be plain, wholesome, and nutritious. In the period of convalescence, tonics and change of air, or, failing this, daily exercise in the open air, are advisable. When complications arise they must of course be treated specially. But they need no treatment distinct from that of the same affections occurring under other circumstances.

---

#### IV. MUMPS (*Parotitis*)

*Definition.*—A contagious fever, of which the chief characteristic phenomenon is inflammation of the salivary glands.

*Causation.*—Mumps, like scarlet fever, measles, and whooping cough, is a malady which is generally present among us in a greater or less degree, and every now and then assumes an epidemic character. Like them, moreover, it is extremely infectious, infects, as a rule, but once in a lifetime, and may be regarded as mainly a disease of childhood. It is not, however, confined to childhood, and unprotected adults, and even persons of advanced age, may suffer from it. It is probably not influenced by sex; and there is no reason to believe that its prevalence depends, in any degree, on season, weather, or climate. The virus of mumps seems to be contained principally, if not solely, in the breath.

*Symptoms and progress.*—The incubative period of mumps probably varies between two and four weeks. Usually it is twenty-one days. The invasion of the disease is sometimes indicated by febrile symptoms and headache, on which, after a few hours or a day or two, parotid inflammation supervenes; but, in many cases, the affection of the parotid gland precedes the febrile phenomena, or accompanies them from the first. The patient usually complains of aching and tenderness behind one of the ascending rami of the lower jaw; and, in a short time, a little fulness is perceived there, completely obliterating the groove normally existing in that situation. But occasionally the inflammation begins in that part of the parotid which lies upon the masseter muscle. The aching, tenderness, and swelling gradually increase for three or four days, until

the whole of the parotid region is occupied by a dense elastic tumour, which extends forward over the masseter muscle, and downwards below the angle of the jaw, and over which the skin may assume a rosy hue. Sometimes the inflammation remains limited to one parotid gland; but more frequently it involves both parotids, and both submaxillary glands as well, attacking them successively at short intervals, so that all become implicated in the course of two or three days. The inflammation spreads also to surrounding parts, and especially to the fauces and tonsils. When the affection embraces all the glands, and is fully developed, the swelling (which then involves the parotidean and inferior maxillary regions of both sides) marvellously alters the character of the face, giving to its sides great fulness and breadth, and adding beneath a large double chin. The glandular affection generally reaches its full development in from three to six days, and remains stationary for a day or two longer. During the whole of this period the swollen parts are firm and tense, very tender on pressure, and attended with much aching, which becomes exceedingly severe when the jaw is moved, and even when the act of deglutition is performed. Hence the patient cannot masticate, and has much difficulty in swallowing, and the saliva tends to accumulate in his mouth. The febrile symptoms, moreover, continue—the temperature sometimes attaining a height of  $103^{\circ}$  or  $104^{\circ}$ ; and there is more or less thirst and anorexia. The character of the saliva, and its quantity, are not usually altered, at all events not altered materially. After a time, which varies according to the severity of the case, and rarely exceeds a week, the swelling of the glands begins to subside, and therewith all the general symptoms. The whole duration of the illness may be a week, but more frequently extends to ten or twelve days or a fortnight; but even at the end of that time the shrunken submaxillary glands may often still be felt of almost stony hardness. Occasionally the skin over the swollen regions desquamates.

It sometimes happens in the course of mumps (either in the period of decline, or more rarely after it has apparently disappeared) that in the male one or both of the testicles get enlarged and painful, and in the female inflammatory swelling of the mammæ or labia comes on. These complications appear generally without warning, but at times are preceded by apparently unaccountable symptoms of the most alarming kind—such as severe collapse, or high fever with delirium. They subside in the course of a few days. Atrophy of the testicle occasionally follows. Swelling of the testicle is very exceptionally the first indication of the presence of mumps.

Mumps is a disease of little gravity, and rarely, if ever, terminates in death. But it is apt to leave behind it a good deal of feebleness of health. It is most likely to be confounded with non-specific inflammation of the parotid, and inflammatory enlargement of the cervical lymphatic glands; but under any circumstances the confusion can only be temporary.

*Morbid anatomy.*—So little opportunity is afforded of investigating the morbid anatomy of mumps, that little can be said positively on the subject. The salivary gland inflammation probably differs anatomically in

no respect from that arising from other causes, but it never proceeds to suppuration. There is doubtless considerable infiltration of the connective tissue of the glands; and indeed the infiltration extends beyond the limits of these organs, involving the connective tissue beneath the skin on the one hand, and that of the fauces on the other.

*Treatment.*—Persons suffering from mumps should be kept out of draughts, and, if not confined to the bed or sofa, at least debarred from making active exertion. The swollen parts may be relieved by fomentations or the application of flannel or cotton wool. The bowels may be kept slightly open. The patient should be fed, during the ingravescence of the disease, on milk, bread and milk, eggs, and other like foods, which need no mastication. When alarming symptoms show themselves, ammonia and other stimulants are indicated.

---

## V. MEASLES (*Rubeola. Morbilli*)

*Definition.*—A contagious exanthem, characterised by the presence of catarrh of the respiratory mucous membrane, and a peculiar eruption, coming out on the fourth day. The disease usually lasts between one and two weeks.

*Causation.*—Measles is one of the most virulently contagious of diseases; and although its virus can probably not be so long preserved in an active form by fomites, or in other ways, as the contagia of scarlet fever and small-pox, the presence of a case of measles among a number of unprotected persons will, as a rule, induce a more certain and widespread outbreak of disease than either of the other exanthems would do under similar circumstances. This peculiarity is due, in some measure, to the fact that its contagiousness is fully developed at a very early stage, being at its height on the second, if not the first, day of invasion, and consequently before the specific nature of the attack is revealed. Hence the great difficulty, if not impossibility, of effectually preventing its spread in households and schools. Measles is generally present in a sporadic form, but at irregular intervals assumes an epidemic character, spreading rapidly among those who have not yet suffered from it, and subsiding when its pabulum gets exhausted. It is mainly a disease of childhood; not, however, so much because adults are naturally indisposed to take it, as because, from its constant presence among us, and its extreme contagiousness, almost all persons have it early in life, and are thus protected from subsequent attacks. In exceptional cases, the same individual takes it a second and even a third time; and occasionally the second attack follows so quickly on the first that it constitutes a relapse. This proclivity to repeated seizures occasionally runs in families. In the great majority of cases, however, one attack is permanently protective.

*Symptoms and progress.*—The latent period of measles varies like that of all other similar diseases; its extreme limits are probably seven

and twenty-one days. When the disease has been given by inoculation with the nasal mucus, the first symptoms are said to have manifested themselves on the seventh or eighth day. But when it is caught, in the usual way, by inhalation of the virus, the incubative period is generally from twelve to fourteen days.

During this time the patient, with rare exceptions, is apparently in good health, but occasionally he suffers from lassitude, debility, and slight febrile disturbance. The invasion of the disease is marked by catarrhal symptoms, in association with slight fever. Chills or slight rigors occur, with elevation of temperature and acceleration of pulse; and, at the same time, the mucous membrane of the nose gets injected and irritable, and secretes a thin mucus, and there is frequent sneezing and sometimes epistaxis. The catarrhal affection speedily extends: to the frontal sinuses, causing frontal headache; to the eyes, causing congestion of the conjunctivæ, watering, and intolerance of light; to the fauces and mouth, inducing patchy redness; and to the larynx, trachea, and bronchial tubes, causing soreness, hoarseness, and a hacking cough. Occasionally, in children, the disease is ushered in with an epileptiform convulsion, or several such convulsions; while, on the other hand, not unfrequently the initiatory symptoms are so slight as to escape observation. During the period of invasion the skin is mostly dry, though sweating may come on from time to time, especially after the rigors; the tongue remains natural or becomes somewhat furred; there is loss of appetite, sometimes sickness and thirst, swimming in the head, and occasionally on the third day some remission of symptoms.

On the fourth day (inclusive) after invasion (sometimes a little earlier, sometimes later) the catarrhal symptoms and fever become aggravated, the temperature rises, the pulse quickens, the patient gets dull and perhaps a little confused, diarrhœa sometimes comes on, and the characteristic eruption begins to appear. This first shows itself on the forehead and temples, near their junction with the hairy scalp, on the cheeks, chin, and back of the neck, whence it gradually diffuses itself over the general surface from above downwards, invading first the chest and arms, then the abdomen and legs. Hands and feet are both affected. It usually becomes most developed on the back of the trunk, and probably least on the generative organs and neighbouring parts of the abdomen. The rash attains its height generally in a couple of days (on the sixth day of the disease), sometimes in three or four, and then declines in the order of its appearance. Its subsidence is followed, in ten days or a fortnight, by a very fine scurfy desquamation, which is chiefly observable about the forehead and cheeks. The severity of the symptoms continues to increase so long as the rash itself increases; and, with the height of the eruption, the temperature attains its highest point, which rarely exceeds  $103^{\circ}$  or  $104^{\circ}$ . When, however, the eruption begins to fade (namely, on the sixth day, or it may be a little earlier or later), the temperature almost suddenly falls several degrees, the severe symptoms subside, and convalescence commences. The temperature in some cases

at once sinks to the normal, but more frequently it descends to  $101^{\circ}$  or  $100^{\circ}$ , at which elevation it remains for a day or two, and then reaches the healthy level, or even sinks below it.

The catarrh of measles is very characteristic and important. It usually commences in the nose, and extends as has been already described. In favourable cases it involves simply the discomforts of ordinary catarrh. But it may assume a more serious character: sometimes it induces inflammation of the eyes, which may terminate in chronic or in purulent ophthalmia, and even in their destruction; sometimes it reaches the tympanum, through the eustachian tube, causing earache and deafness, upon which suppuration of the middle ear or permanent deafness may supervene; and very often croupy symptoms manifest themselves, or acute bronchial catarrh, or capillary bronchitis.

The tongue may be clean, or covered with a whitish-brown fur, but does not usually get dry. Occasionally, however, when typhoid symptoms manifest themselves, it becomes both dry and black, and sordes appear on the teeth and lips. There may generally be seen, early in the disease and before the appearance of the cutaneous eruption, spotty redness of the palate and fauces, of the inner surface of the cheeks and lips, and of the gums. This often gets uniform and intense, especially on the gums and at the back of the mouth, and is sometimes attended later on in the disease with aphthæ or excoriation, and ulceration of the gums. Gangrene of the mouth is met with in rare cases. Sickness is by no means a constant symptom, and seldom lasts beyond the period of invasion. Diarrhœa frequently comes on with the eruption, and is often very troublesome. Sometimes late in the disease it assumes a dysenteric character. The urine is scanty and somewhat high-coloured, and often deposits a sediment of urates. Albumen is occasionally present in it during the height of the fever.

The eruption on its first appearance has a dusky pink colour; it consists of small, slightly-elevated papules, which gradually increase in area until they attain a line or even two lines in diameter. They are darkest at the centre and fade towards the periphery, and are momentarily effaced by pressure. They are at first discrete, although arranged in groups which have a tendency to form irregular crescents or circles. When they have attained their full size, however, neighbouring spots often run together; and sometimes, where the rash is very thick, an extensive area of nearly uniform redness results. Whilst the eruption is well marked, there is always more or less subcutaneous infiltration, and the face appears swollen, and the hands and feet feel tight and uncomfortable. The spots fade very quickly; but, for the most part, there remains some pigmentary discoloration, and perhaps, too, some slight tendency in the vessels of the affected spots to dilate under excitement, which collectively render indications of the rash visible long after the actual rash has disappeared. The skin is generally hot and dry. Gangrene of the vulva occasionally occurs in young children.

The presence of frontal headache has already been adverted to. The

chief other pains to which patients are liable are those connected with the occurrence of diarrhœa or dysentery, and otitis. If young children seem to be in severe and continuous pain, the latter complication may be suspected. Patients, especially children, are somewhat dull and irritable, and occasionally, during the earlier period of the eruptive stage, slightly delirious. Marked delirium is unusual, except in severe cases, and cases assuming a typhoid character. In the latter, coma or convulsions sometimes come on. Convulsions in the eruptive stage are far more serious than those occurring during the period of invasion.

Measles, if unattended with any serious complication, is commonly a mild disorder, convalescence from which commences about the sixth day and is completed by about the tenth. Sometimes it is so little developed that its presence is only indicated by slight feverishness and fretfulness, and an inconspicuous rash about the cheeks and back of the neck, associated or not with catarrhal symptoms. In such cases the patient may be well within three or four days from the first manifestation of symptoms, and it may be impossible by these alone to recognise his disease. Sometimes the attack of measles is inherently very severe, and such severity of attack occasionally characterises epidemics. In this case the patient manifests obvious prostration from the beginning; the pulse is rapid and feeble; the eruption is scanty and of a dusky hue, sometimes almost black, or petechial; the lungs get congested; typhoid symptoms, characterised by black tongue, tremulousness, and delirium, soon come on; and the patient dies collapsed, perhaps comatose, at an early period. When the crisis is delayed beyond the sixth, seventh, or eighth day, the cause of the delay is generally the supervention, or aggravation, of one of the ordinary complications of the disease, especially laryngitis, bronchitis, lobular pneumonia, or pneumonia. These in fact constitute the main causes of the unfavourable results of measles. Death, however, may ensue from any of the other complications which have been enumerated, namely, diarrhœa, dysentery, epistaxis, gangrene of the mouth or other parts, or the results of otorrhœa. Pulmonary phthisis is a not unfrequent sequela of measles, following upon the more common pulmonary or bronchial inflammation. Diarrhœa of a very persistent and troublesome character often comes on after measles in children.

*Morbid anatomy.*—Internal organs manifest no post-mortem appearances peculiar to measles. If the patient die early, or of the malignant form of the disease, the blood is dark-coloured and coagulates imperfectly, and there may be hypostatic congestion of the lungs, and congestion of other organs. Later on, we necessarily detect the lesions which have been instrumental in causing death—lesions chiefly of the air-passages and lungs, or bowels.

*Treatment.*—The patient, for the sake partly of counteracting spread, partly of preventing aggravation of the various mucous inflammations by exposure to cold, should be confined to his room, and, if possible, kept in bed until febrile symptoms have entirely subsided. His room should be airy and well ventilated, but of an agreeable temperature, and he should

be carefully protected from draughts or chills. It is not generally necessary that medicines should be given; but, partly to promote the excretions, and partly to relieve the irritation of the respiratory mucous surface, a mixture containing a small quantity of ammonia with the acetate of ammonia, to which may be added ipecacuanha wine and minute doses of laudanum (very minute in the case of young children) may be frequently administered; and for the soreness of the throat a little black-currant jelly may be used, and the patient may gurgel with warm milk. In consequence of the tendency to dysenteric diarrhœa, purgatives should be avoided, or employed with great caution. The diet should be mainly bread and milk, beef-tea, and other such fluid, bland, nutritious articles of food. When convalescence is in progress, vegetable tonics are useful, and a substantial diet must be gradually adopted. The various complications of the disease, and its sequelæ, will require each its appropriate treatment, which need not differ materially from that of the same affection occurring independently; only it is important to recollect that depletory measures are in this case specially injurious. When the eruption is dusky, or comes out imperfectly, and the patient at the same time appears to be very ill, a warm bath is often of great service. It may also prove beneficial when, late in the disease, convulsions come on. When the patient shows signs of exhaustion, and especially therefore in the malignant form of the disease, and when typhoid symptoms are present, stimulants are imperative. In most cases of measles they are quite unnecessary.

## VI. EPIDEMIC ROSEOLA (*Rötheln. Rubeola*)

*Definition.*—A contagious disorder having a close resemblance to measles, with which it is often confounded.

*Causation.*—This disease is said to occur chiefly in hot seasons, and to affect children much more readily than adults. It is doubtful, however, whether season or age exerts any special influence over it. It certainly spreads by contagion, and doubtless, therefore, depends on a specific virus. Its contagiousness is apparently much less active than that of measles.

*Symptoms and progress.*—The incubative period of epidemic roseola appears to be variable. Dr. Squire says it is generally a fortnight, but ranges between six and twenty-one days. In one case under our care, about which there could be no dispute, it was exactly five days. Its invasion, in many cases, is coincident with the appearance of the rash, or at any rate invasion and rash occur on the same day. Not unfrequently, however, the eruptive period is preceded by a day, possibly two, of poorliness: the patient has a headache, is feverish, and may even have rigors; or he complains of cold or catarrh; or he has pains across the loins and polyuria; or, according to Trousseau, he may, if a child, have diarrhœa and convulsions. The latter occurrences, however, must be very

rare; and, indeed, among the chief distinctions between this affection and measles are the slightness, the want of character, and the uncertain but always short duration of its stage of premonitory fever.

The rash generally appears first on the sides of the nose and adjoining parts of the cheeks, the lower region of the forehead, and the lateral aspects of the inferior maxilla; but it shows itself almost, if not quite, as early on the forearms and hands, and corresponding parts of the lower extremities, and then rapidly diffuses itself over the whole cutaneous surface. It usually attains its height on the second day, and, in the course of the next two, three, or four days, rapidly disappears. The rash has much resemblance, in tint and general appearance, to that of measles, but is said not to assume the crescentic grouping which is characteristic of that affection. This latter statement, however, is not absolutely true. The spots, which fade on pressure, are of a dusky red or purplish hue, of irregular shape and often clustered (sometimes running together over considerable tracts), and vary in size from mere points up to a line or more in diameter. They are, for the most part, scarcely elevated above the general level of the skin; but occasionally, and more especially on the face, form considerable papular or tabular elevations. The rash is generally most abundant on the face, where it is often confluent, and on the forearms and legs (especially about the ankles and wrists), where also there is often a similar tendency to confluence. It is less thickly developed elsewhere, but no part is free; and, generally, abundant discrete spots may be observed on both the palmar and the dorsal aspects of the hands and fingers, and on the corresponding parts of the feet and toes. It may appear only on the extremities. It is attended with considerable itching, and is often followed by branny desquamation. The patient does not generally complain much, possibly not at all, of soreness of the eyes, or lachrymation; nevertheless there is nearly always marked congestion of the conjunctivæ. There is frequently sore throat; and sometimes red puncta, or more or less diffused redness, may be recognised on the soft palate and fauces. There is not, as a rule, defluxion from the nose or sneezing, or, if these symptoms are present at all, they are by no means prominent. There is often a little cough. During the first day or two after the appearance of the rash, the patient may be somewhat feverish, with slightly elevated temperature (it may, however, reach  $103^{\circ}$ ), headache or swimming in the head, and other slight symptoms referrible to fever; but not unfrequently he feels and expresses himself as being perfectly well. The affection is unattended with complications, subsides ordinarily within a week, and has no sequelæ. The lymphatic glands in the neck are said to become enlarged early in the disease. We have not observed it as a distinctive feature, and know that, at any rate in a large proportion of cases, no such enlargement ever takes place.

Epidemic roseola has been described as a hybrid of scarlet fever and measles, and some have regarded it literally as such. There is little likeness, however, between it and scarlet fever. Its resemblance to measles, on the other hand, is very close. It differs from measles, chiefly in the

slightness and short duration of its initiatory fever, in the almost complete absence of coryza, and in the general mildness of its symptoms; but these differences are chiefly of degree, and only such as might be observed between very slight and severe cases of true measles. The main distinctions are these: that roseola and measles are mutually unprotective; that roseola is of frequent occurrence in those who have had measles only a short time previously; and that when it breaks out in a family or school of children, of whom some have had measles and some not, it attacks them indiscriminately, and with equal mildness, and never develops into true measles.

No special *treatment* is needed.

---

## VII. SCARLET FEVER (*Scarlatina. Febris Rubra*)

*Definition.*—A contagious malady, characterised mainly by a general punctiform scarlet eruption, usually appearing on the second day, and by inflammation of the fauces, tonsils, and kidneys.

*Causation and history.*—Down to the sixteenth or seventeenth century scarlet fever was confounded with measles. Yet they are two perfectly distinct diseases, and are now fully recognised as distinct. Whatever its original source, or however it may formerly have been limited in area, it is now general throughout the world, occurring in most parts sporadically, but frequently breaking out into epidemics of greater or less severity. Its prevalence seems independent of season or climate, but, as with other infectious epidemic disorders, is largely promoted by overcrowding and poverty. Children suffer from it in much larger proportion than adults; not, however, because there is any special proclivity to it in childhood, but because, from its frequent prevalence and highly infectious nature, the great majority of children are exposed to its influence during the first few years of life, contract it, and thus acquire protection. Scarlet fever rarely occurs a second time; yet second and even third attacks have been noticed. It is a common observation, however, that protected attendants on scarlatinal patients frequently suffer from sore throat during the period of their attendance, and the question naturally arises, whether such attacks should not be regarded as abortive attacks of scarlet fever. They probably are so. The contagion of scarlet fever is very powerful and diffusive. It may be carried considerable distances by the atmosphere—certainly through the whole dimensions of a large ward; it clings to clothes and other fomites with great tenacity, and may thus lie latent, yet capable of action, for an indefinite period; and it is liable to infect milk and other articles of food exposed to its influence. Scarlet fever occurs only as the result of contagion, usually conveyed by the means which have already been indicated. It seems that it may also be transmitted by direct inoculation. For there is reason to believe that it can be imparted by inserting the fluid of the scarlatinal vesicles beneath the cuticle of persons who have not yet had it;

and it is certain that women, at the time of parturition, are specially liable to take it, receiving it then, in some cases, apparently direct from the fingers of the accoucheur. The time at which a scarlatinal patient begins to be infectious is uncertain. We know, however, that his infectiousness is not very well marked during the first two or three days. It probably increases with the development of the rash and sore throat, and pretty certainly does not cease until desquamation has been completed.

*Symptoms and progress.*—The incubation of scarlet fever is shorter than that of most diseases of the same class. It usually varies between six and eight days, but is occasionally longer, and very often less. Many cases, indeed, of undoubted authenticity have been recorded in which it certainly did not exceed twenty-four hours. Especially in puerperal women, and probably also in persons suffering from large wounds, the period of latency seems generally to be of very short duration. Scarlet fever varies, perhaps, more than any other like disease, alike in the degree of severity of its attacks, in the symptoms which it presents, and (in fatal cases) in the cause and period of death. In a typical case, the invasion is sudden, and usually marked by chills, vomiting, and sore throat; with which are associated, or on which soon supervene, great rise of temperature, general dryness of skin, much acceleration of pulse, languor, drowsiness, frontal headache, giddiness, aching in the limbs, slight coating of tongue, thirst, anorexia, and sometimes diarrhoea. The most characteristic of these symptoms are: the sore throat and vomiting; the remarkable rise in the frequency of the pulse, which may attain 120 in the adult or 160 in the child; and the rapid augmentation of temperature, which may reach very nearly  $105^{\circ}$  during the first day. The disease is sometimes ushered in with rigors, and not unfrequently there is some delirium or even tendency to coma.

On the second day, the rash makes its appearance, first on the chest, and simultaneously or very soon afterwards on the forearms, lower part of the abdomen, and upper part of the thighs. It becomes general in the course of four-and-twenty hours, more or less, and attains its full development on the third or fourth day. It consists, in the first instance, of very minute rosy papules, due for the most part (as those of so-called 'goose's skin') to the conical elevation of the cutis around the points of emergence of the hairs; hence they are closely and pretty uniformly arranged, but discrete and separated from one another by healthy skin. But they soon increase in size and intensity of redness, and presently, blending with one another by their congested margins, give to the surface a uniformly scarlet hue. The papular character, however, of the rash is still, for the most part, distinguishable on close inspection. Not unfrequently the papule on the chest and sides of the neck become vesicular; and generally the rash is attended with more or less infiltration and thickening of the cutis. Very rarely, either when the rash is at its height or at the beginning of its decline, serous fluid is poured out extensively beneath the epidermis, especially that of the trunk, so that the surface becomes covered with small flat blebs, which tend to run together—a condition which leads to a larger and coarser desquamation than usually occurs. The vivid redness

of the skin disappears readily on pressure, as by drawing the point of the nail firmly along the surface; and the line thus formed remains anæmic for a second or two. The scarlatinal rash varies much in its intensity and in its diffusion. It is sometimes very pale and almost imperceptible; and it may be strictly limited to the parts in which it usually first appears. When general, it is most vivid on the neck, chest, abdomen, and inner aspects of the thighs and arms. It is rarely distinct upon the face, which, however, often presents irregular patches of redness. The feet and hands are not unfrequently stiff with it, and its attendant œdema.

While the rash is attaining its full development, the other symptoms are all undergoing aggravation. The heat rises; the pulse increases in frequency; the respirations grow more rapid; the tongue, which was at first covered (excepting at the tip and edges) with a thickish whity-brown fur, soon cleans, and towards the end (that is, in four or five days from the invasion) becomes morbidly red, with swollen papillæ, and presents the remarkable strawberry-like appearance so characteristic of this disease. At this time too it is apt to get dry. The soreness of the throat increases; and, on inspection, more or less vivid or dusky redness of the pillars of the fauces, soft palate, uvula, and tonsils, is apparent. These parts, moreover, swell; and the tonsils often enlarge as in common quinsy, and present here and there on their surface imbedded, or adherent, spots of inspissated secretion. With the faucial swelling and inflammation are usually associated pain and difficulty in swallowing, fulness and tenderness behind the angles of the jaw, and some enlargement of the neighbouring lymphatic glands. The patient's muscular weakness increases, and his limbs get tremulous; he becomes and looks dull and stupid, or restless, is forgetful, and slow to answer; delirium probably increases; vomiting is now not common, but thirst and anorexia continue; and the bowels, though variable, are generally constipated.

From the fourth to the sixth day of the disease, the rash begins to fade; and it disappears, according to its intensity and the date at which it attained its maximum, between the sixth and twelfth day of the disease, or between the fifth and tenth day from the commencement of the rash. It is frequently about this time that, if the case be going on badly, the patient passes into a typhoid condition, or throat complications become serious (the tonsils suppurating, ulcerating or sloughing), or the urine gets albuminous, and anasarca and uræmia supervene. If, however, the case be going on favourably, all the symptoms now gradually subside; the temperature, with slight daily remissions, ere long becomes normal or even subnormal; the pulse by degrees sinks to its healthy rate or below it; the soreness and inflammation of the throat subside; the tongue gets clean and moist; thirst abates; appetite returns; and delirium, with other symptoms referrible to the nervous system, vanishes.

With the disappearance of the rash, desquamation commences. It may be observed, indeed, on the chest before the rash has quite left other parts of the surface. It usually begins on the neck and chest; whence it spreads to the rest of the trunk, and then to the limbs, involving lastly the palms

of the hands and soles of the feet. Desquamation always takes place in considerable flakes, the size of which is greater according as the epidermis is thicker. Hence, they are small and delicate on the chest and abdomen, large on the limbs; and from the hands and feet the epidermis occasionally separates in the form of a glove. Desquamation, indicated at first by the formation of a transverse fissure at the root, sometimes affects the nails. The period of desquamation is of very various duration; it is sometimes completed in one or two days, not unfrequently extends over a week or two, and occasionally is prolonged for several weeks. It is a period of some danger; for it is chiefly then that albuminuria arises, that dropsy and uræmia threaten, and that rheumatism and other serious sequelæ are liable to come on; moreover there is good reason to believe that the desquamating particles of skin are charged with the contagium of the disease, and are highly infectious.

We will now pass briefly in review some of the more important phenomena of scarlet fever. Acceleration of the pulse, especially in children, is a notable feature of the disease; it probably rises on the first day to between 100 and 120—in children still higher; and it generally continues to increase up to the time of full development of the rash, sometimes attaining a rate of from 120 to 160, or more; after which, if the case go on favourably, it gradually falls. This great acceleration of pulse is not necessarily an indication of danger. Nevertheless, unusual rapidity, with marked weakness of pulse, especially when associated with other unfavourable symptoms, is of grave import.

Respiration is always more or less hurried, but there is not necessarily any cough or difficulty of breathing. Sometimes, however, in cases of great intensity (as also in pyæmia and other forms of so-called 'blood-poisoning') the respirations become very rapid and shallow, and the inspirations attended with dilatation of the nostrils, and a sniffing or sucking sound—conditions which, unassociated with distinct pulmonary lesion, indicate very great danger. During the latter part of the eruptive stage, or subsequent periods of the disease, inflammation may extend to the larynx and trachea, and produce the usual symptoms of laryngitis; or coryza, bronchitis, or lobular or lobar pneumonia, with their several groups of symptoms, may come on.

Thirst and loss of appetite are always present in a greater or less degree. Vomiting is for the most part a characteristic feature of the invasion, and few children fail to suffer from it; but it does not usually persist. Diarrhœa is not uncommon at the commencement; after which the bowels are generally, but by no means necessarily, constipated. The tongue varies in character: in very mild cases it is only slightly furred, and soon cleans, without ever displaying the strawberry-like appearance; sometimes it very early becomes thickly coated, dry, and even black, sordes appearing at the same time on the teeth and lips; but more frequently, as has been pointed out, it is coated at the beginning, and on the fourth or fifth day gets clean and unnaturally red, with prominent and swollen papillæ; after which it may either gradually acquire the normal characters

or become dry and mahogany-like. The soreness of the throat causes difficulty and pain in swallowing and a nasal quality of voice. It involves all the parts at the back of the mouth, the fauces, and the upper part of the pharynx, but does not usually include the larynx. The tonsils chiefly suffer; and, as has been pointed out, they generally get enlarged, and present on the surface opaque patches, which have been secreted by the glandular follicles. In mild cases, the soreness may be very slight, and may speedily subside. Very often, however (sometimes at the beginning, more frequently in the second or third week), the tonsils suppurate, ulcerate, or slough; or abscesses and buboes form in their neighbourhood; or a false membrane appears upon the surface and extends to other neighbouring parts.

The urine, during the febrile stage of the disease, is scanty and high-coloured, contains a diminished quantity of chlorides, and not necessarily, according to Dr. Gee, any increase of urea. Subsequently it becomes more abundant and of lower specific gravity. Albuminuria is frequently present, and its presence is a matter of importance. It appears to have no particular connection with the degree of severity of the attack. Indeed, many of the severest cases escape it altogether, and many of the mildest suffer severely. The time of the first appearance of albumen varies. It has been detected on the second or third day of the disease, but commences far more commonly in the course of the second or third week, or during the period of desquamation. Its amount varies, as also does the period during which it persists. The urine is not unfrequently smoky. Under the microscope are found hyaline and epithelial casts of the renal tubules, and usually also blood-corpuscles, or casts containing altered blood.

The characters of the rash have already been fully described; it must be added that, during the height of the disease, the skin is generally dry and feels pungently hot, and that in 'malignant cases' petechiæ often make their appearance.

The temperature of the body attains a greater height in scarlet fever than in any other disease of the same class; it frequently reaches  $104^{\circ}$  or  $105^{\circ}$  when the eruption is fully developed, and occasionally rises to  $110^{\circ}$  or even  $112^{\circ}$ . It differs in its course from that of small-pox, in the fact that it rises, instead of falling, when the rash appears; and from that of measles, by subsiding slowly after the rash has reached its acme, instead of undergoing a sudden fall.

The patient complains of soreness of throat, and has some headache and giddiness, with general aching of his limbs; but the pains are not so severe as in many other febrile disorders. In the beginning of the disease he is generally restless and sleepless, and often a little delirious. When the eruption comes out, and during its persistence, he may still be restless and excited, or dull and inclined to coma, or he may have more or less delirium. In grave cases, violent delirium is sometimes one of the earliest symptoms. On the other hand, delirium of an alarming kind may arise at various stages of the disease without necessarily implying serious danger. In one such case, in a boy of about sixteen, on the fifth day of

the disease, when the rash was fading, the temperature falling, and the urine free from albumen, busy delirium, like that of delirium tremens, came on. This continued with wakefulness for six-and-thirty hours; at the end of which time, without the aid of drugs, he fell suddenly into a profound sleep, lasting for twenty-four hours, when he woke sensible, and advanced in convalescence. Symptoms of acute mania also may arise, as in other acute febrile diseases, without necessarily endangering the patient's ultimate recovery. Occasionally, in children, convulsions come on early in the disease; they are rarer, however, than at the commencement of measles or small-pox, and are far more serious—indeed are generally followed by a fatal result. Coma, delirium, or convulsions not unfrequently usher in death. Tremors of the muscles, subsultus, and picking at the bed-clothes occur in serious cases.

No known disease is more unequal in its attacks than scarlet fever. In individual cases it often proves one of the mildest and most trivial of ailments, often one of the most terrible and rapidly fatal of plagues. In one household all the members may have it so slightly that they scarcely acknowledge to themselves that they have been ill; and in another not one that is attacked survives. And varieties of this kind characterise epidemics. Thus, in many cases, the disease spreads rapidly through a village or town, or over a large extent of country, and its attacks are so mild that scarcely a death results; while in other cases the epidemic is characterised by great malignancy and terrible mortality.

The mildest form has been termed *latent scarlet fever*. In this the cases are so slightly developed that they would probably not be recognised as scarlet fever at all, were it not for the fact, either that they occur while scarlet fever is prevailing, or that they impart scarlet fever, or that desquamation, or albuminuria with anasarca, or both, supervene. The patient may suffer from slight febrile symptoms only, lasting for a day or two, with which may, or may not, be associated evanescent traces of a rash, or some degree of roughness of the throat. It is a question, which has already been raised, whether the sore throat, which protected attendants on scarlatinal cases so frequently experience, is not the visible sign of latent scarlatina, or rather perhaps of the disease in a modified form.

The more ordinary form of scarlet fever is that to which the previous detailed description applies. The symptoms of invasion are well marked, the rash is abundantly developed, the throat and tongue are typically affected, and the rash disappears between the sixth and the twelfth day of the disease, to be followed by desquamation. But cases of medium severity may present considerable varieties among themselves. Thus, in some, while every other characteristic symptom is present, the throat may escape; in some, while the throat suffers severely, the eruption may be imperfectly developed. The former cases are often spoken of as *scarlatina simplex*; the latter as *scarlatina anginosa*.

The epithet *malignant* is commonly applied to those cases of scarlet fever in which the symptoms are unusually severe, and death tends to come on rapidly. It is somewhat loosely applied, however, and embraces

cases of widely different characters. The most terrible of such cases are probably those in which the patient seems to be struck down by the severity of his attack, and dies collapsed during the first three days of the disease: sometimes on the first day, often before the rash has had time to appear or to develop, or before the affection of the throat has become a special cause of complaint. The symptoms of invasion are severe; the vomiting probably is distressing; the chills or rigors are unusually well marked; the temperature attains an extraordinary elevation; the pulse becomes extremely rapid and weak, the respirations quick, shallow, and suspirious; prostration and muscular debility are extreme—there is tremulousness of the muscles and jactitation; the face is dusky and the expression anxious. The patient is sometimes sensible, almost to the last; sometimes there is from the beginning fierce or muttering delirium, which lapses before death into coma, occasionally preceded by an attack of convulsions. Another variety of malignant scarlet fever is that in which the throat is gravely implicated. The throat-affection may be serious from the first; but more frequently, in a case which presents no very unusual features at the beginning, it undergoes aggravation either at the acme of the fever or during the subsidence of the rash, or even on its disappearance. The nature of the affection has already been adverted to. There may be abscess of the tonsil, or ulceration or gangrene, with œdema of the surrounding tissues; and, supervening thereon, the glands in the neck may inflame and suppurate, and sinuses form. Under these circumstances the patient is apt to fall rapidly into a typhoid condition, and so die; or he may be carried off by œdema of the glottis, perforation of an artery, or pyæmia. Scarlet fever occurring at or just subsequently to parturition is excessively fatal, and constitutes one of the gravest forms of so-called ‘puerperal fever.’ It does not appear, however, to be specially dangerous during pregnancy, or to lead to abortion.

The sequelæ of scarlet fever are numerous and important. It is difficult, however, to make any clear distinction between the complications which form an essential part of the disease, and have already been described, and the phenomena which are simply secondary. It is needless to repeat what has been said about bronchitis, pneumonia, and ulceration of the throat, all of which are apt to complicate the disease in its later stages. We will briefly consider the more important of those sequelæ which have not yet been referred to. First, the conjunctivæ not unfrequently inflame in the course of scarlet fever; and occasionally in the second or third week of the disease the ophthalmia becomes intense and purulent, and sloughing of the corneæ may result. Second, inflammation sometimes extends along the eustachian tube to the tympanic cavity, producing ear-ache or otitis, with disease, maybe, of the petrous bone, and, possibly, sooner or later, abscess of the brain, pyæmia, or some other fatal lesion. Inflammation may extend also to the nose, and produce chronic catarrh of its mucous surface. Third, inflammation of the pericardium or of the pleuræ (the latter often purulent) is not uncommon. Fourth, during the decline of the fever, or even during the period of

convalescence, rheumatism is very apt to supervene. This differs in no respect from ordinary rheumatism, involves successive joints and in many cases the pericardium or the cardiac valves, and adds seriously to the fever and distress of the patient. To scarlatinal rheumatism, as to other varieties of rheumatism, chorea or embolism occasionally succeeds. Fifth, the most important sequelæ of all are, undoubtedly, anasarca and uræmic poisoning. We have pointed out that in a large proportion of cases (and for the most part in the second or third week) the urine becomes albuminous. Now this condition generally passes off without any ill result. But not unfrequently, and more frequently after mild than after severe cases, anasarca and uræmia come on, which may presently be attended with severe headache, and followed by epileptiform convulsions and death. Under judicious treatment the albuminuria and the dropsy may subside; but sometimes the urine remains permanently albuminous, and the kidneys undergo slow disorganisation. It may be observed that anasarca sometimes survives the disappearance of the albuminuria, and that it is sometimes developed in those who have never had albumen in the urine. Uræmic convulsions generally involve a fatal issue.

*Morbid anatomy.*—On post-mortem examination of scarlatinal patients most internal organs appear to the naked eye fairly healthy. The liver and kidneys may be somewhat softer than natural, and the blood imperfectly coagulated. Yet, well-formed fibrinous clots are not uncommon in the right ventricle. In so-called ‘malignant’ cases there may be collapse and hypostatic congestion of the lungs, and hemorrhage into and at the surface of internal organs. The throat generally presents distinct traces of inflammation and ulceration. The solitary intestinal glands and Peyer’s patches are somewhat enlarged. The only other morbid appearances (and they are sufficiently important) are such as are connected with the sequelæ and complications of the disease. These, however, though common in scarlet fever, are not peculiar to it, and will be considered with the special diseases of the various organs to which they belong, or under other appropriate heads. The microscopic morbid anatomy of scarlet fever has been investigated with minute care by Dr. Klein,<sup>1</sup> who shows that even at the earliest stages of the disease there is a marked tendency to inflammatory hyperæmia and proliferation, not only in the skin, mouth, throat, and kidneys, but throughout the alimentary canal, and in the salivary glands, pancreas, liver, lymphatic glands, and spleen. Generally in all these parts there are observed germination of the endothelium of the small blood-vessels, hyaline thickening of the intima, germination of the nuclei in the muscular coat, and accumulation of lymphoid cells in the tissues around; besides which, in the epidermis, swelling and proliferation of the cells of the rete mucosum, with serous effusion and migration of leucocytes between them, and tendency to detachment of the horny-layer; in the various epithelia (including those of the renal tubules) changes resembling those in the skin; and in the

<sup>1</sup> See Report of the Medical Officer of the Privy Council. New Series, No. viii. p. 23 *et seq.*

interior of lymphatic glands, especially those of the neck, disappearance of the lymphoid cells, and development in their stead of many-nucleated giant-cells, which ultimately become fibrous. A more minute description of the changes which take place in the kidneys will be given hereafter.

*Treatment.*—Whenever scarlet fever breaks out among a number of susceptible persons the sick should be at once separated from the sound. The patient should be placed in a suitable room, at the top of the house if possible, and if possible should have a floor to himself. All the usual measures should be taken as regards nursing, ventilation, disinfection, cleanliness, and removal of surplus furniture. He should be kept strictly in bed, with only so much covering as is absolutely necessary. His diet should consist of milk, beef-tea, eggs, and other such articles. And for medicine, acetate of ammonia or nitrate or chlorate of potash in solution may be serviceable. Some strongly recommend ammonia in large and frequent doses; and some dilute hydrochloric acid, or the perchloride of iron. Ice is often used to allay vomiting. To relieve the soreness of the throat, ice, or the inhalation of steam, or warm milk slowly swallowed, or astringent or antiseptic gargles may be employed. The patient is generally benefited also by tepid sponging, or the tepid douche bath. If the bowels are much constipated, they should be relieved by laxatives; if there is diarrhoea, they should be restrained by opium or other astringents. When convalescence is taking place, it is recommended to keep the body well greased in order to prevent the dissemination of the flakes of cuticle. The practice is a good one, and may be associated with the daily use of warm baths. Tonics must now be had recourse to, and the diet should be nutritious and include a fair proportion of solid food. It is during this period that the dangers of rheumatism and of dropsy are greatest. It is important, therefore, that the patient should be kept warm, that he should not be exposed to draughts, that he should keep his room (either confined to bed or encased in flannel), and that the excretory functions should be carefully attended to, until the period of desquamation has come to an end.

In most cases stimulants are not needed, but in malignant cases, and all cases where the muscular debility is great, and there is a tendency to collapse, or to the coming on of typhoid symptoms, they are imperatively demanded.

In the severest cases of the disease, however, all treatment is futile; and in the milder cases the care of the physician must be directed, not so much to the cure of the disease, as to the relieving of discomfort, and to the obviation by precautionary measures of complications and sequelæ.

If there be nasal catarrh with discharge, it is well to syringe the nostrils with warm water, or water containing chlorate of potash, nitrate of silver, or some antiseptic. If the throat be ulcerated or gangrenous, solution of perchloride of iron or of nitrate of silver, or even the latter in a solid form, or hydrochloric or nitric acid, may, according to circumstances, be applied. Warm fomentations or poultices should be

employed externally; and if there be suppuration in the glands or connective tissue behind and below the jaw, a puncture or incision should be made. Otorrhœa, rheumatism, renal dropsy, and uræmic convulsions must be treated as these affections are treated when they arise under other circumstances. And so with regard to other complications. Only it must not be forgotten that these affections, occurring as complications, bear depletion less, and need stimulation more, than do the same affections when they are of spontaneous or idiopathic origin.

---

### VIII. SMALL-POX (*Variola*)

*Definition.*—A specific fever, spreading by contagion, and especially characterised by the appearance on the third day of a papular eruption, which gradually becomes pustular, and attains its full development on or about the eleventh day of the disease. The eruption shows itself also in the mucous membrane of the mouth, fauces, and larynx.

*Causation and history.*—As with many other of the infectious fevers, the history of small-pox cannot be traced further back than the Christian era. The first recorded epidemics, indeed, seem to have occurred in the sixth century, since when it has never disappeared from among us, has been carried from Europe and Asia over all parts of the world, and, down to within a recent period, has formed one of the most formidable and fatal of pestilences. The disease was robbed of many of its terrors by the practice of inoculation, introduced first into this country, early in the eighteenth century, by Lady Mary Wortley Montagu, who had witnessed the efficacy of the procedure in Constantinople, whither it had been imported from Persia and China. It was yet more marvellously controlled by the application of Jenner's discovery, made at the end of the same century, of the protective influence of vaccination; since the general adoption of which small-pox has become a comparatively rare and unimportant affection. But it still maintains all its old virulence when it attacks those who are not protected by vaccination or by a previous attack of the disease, and all its old epidemic violence when it is introduced among susceptible communities. Small-pox has no special predilection for age or sex; but it is said that dark-skinned races, and especially negroes, suffer more severely from it than the denizens of temperate climates. All persons, indeed, are liable to take it, unless protected in one or other of the ways which have just been adverted to, or (as rarely happens) by some peculiar constitutional insusceptibility. Instances, however, are, on the whole, not uncommon in which persons have a second and even a third attack—such attacks being for the most part mild; and it is a curious circumstance that those who, in spite of constant exposure, have enjoyed immunity from the disease for many years not unfrequently end by contracting it, and have it in a severe form. Whatever the source of small-pox may originally have been, there is no doubt whatever that it now comes solely

by contagion, and that this may be conveyed either through the atmosphere or by fomites, or by direct inoculation with the contents of the variolous pustules. Few diseases, indeed, are more virulently contagious than small-pox, and there is none whose virus remains effective for a longer period.

*Symptoms and progress.*—The period of latency of the inoculated disease has been distinctly ascertained to be seven or eight days. On the second day a small papule shows itself at the seat of puncture, which by the fourth day is converted into an umbilicated vesicle. On the seventh day the vesicle has formed a pustule, and about the same time the lymphatic glands above have become swollen and tender. And on this day, or on the eighth, rigors and other symptoms indicative of the invasion of the disease occur. About the tenth or eleventh day the pustule is fully developed, and at the same time the general variolous rash appears. By the fourteenth day the pustule has dried up into a scab. The period of incubation is always longer when the disease has been acquired in the usual way. It is generally considered then to range between ten and sixteen days. According to Mr. Marson it is almost invariably twelve days. The facts connected with inoculation prove that the variolous contagium is present, in a concentrated form, in the mature pustules. There can be little doubt, therefore, that small-pox is especially infectious about the period of maturation. But it is probably infectious during the whole period of its duration, from the first signs of invasion up to the separation of the last scab.

The incubative stage of small-pox is, with rare exceptions, unattended with symptoms. But occasionally the patient suffers from languor, peevishness, and other vague feelings of illness. The invasion is more or less sudden, and is indicated by: rise of temperature, chills or rigors, followed by or alternating with heat of skin, and generally (in adults) copious perspiration; severe sickness, with anorexia, thirst, and constipation or (in children) diarrhœa; headache, aching of the limbs, and intense pain in the lumbar region of the spine; drowsiness, and not unfrequently delirium, stupor or coma, and (in children) convulsions. There is sometimes maniacal excitement. The most characteristic of the above symptoms are the vomiting, constipation, and acute lumbar pain; it is important, too, to note the frequency of perspirations, and of convulsions, which for the most part are unattended with danger to life. The symptoms of this stage are severe in proportion to the severity of the attack which they usher in. Other things being equal, therefore, the higher the temperature, the more persistent the vomiting, the acuter the pain in the back, and the more pronounced the implication of the brain, the more quickly will the disease assume grave proportions, and the greater will be its intensity and the prospect of a fatal issue. Absence or scantiness of perspiration, and in adults the presence of diarrhœa, are also indications of a severe attack.

The above symptoms usually attain their maximum on the third day—the day on which the characteristic rash first manifests itself. In a small

proportion of cases, and these are for the most part fatal cases of great malignancy, the eruption appears on the second day ; and occasionally it is delayed to the fourth or even later. In modified small-pox, it is not unusual to find the true eruption preceded for a day or two by a roseolous efflorescence, which has some resemblance to the scarlatinal rash. And in cases which threaten to be severe there may be on the second or third day of the disease, first, a sub-papular patchy redness on the face, trunk, and elsewhere, which is almost undistinguishable from the rash of measles ; or second, an abundant petechial rash chiefly about the sides of the chest and abdomen and on the loins. The true rash usually commences, however, on the third day, in the form of minute reddish papules, which are first visible on the face, head, neck, and wrists, and in the course of the next two days invade successively the upper part of the chest, the arms, the rest of the trunk, and the lower extremities. The spots are hard, solid, hemispherical or acuminate, and feel like shot imbedded in the skin ; they gradually enlarge, and in the course of two or three days get vesicular ; then, still increasing in area, their contents become opaque and milky, and about the sixth day (eighth day of the disease) distinctly purulent. With their conversion into pustules, there is a marked extension of inflammation ; each pock acquires a deep-red areola, and the subjacent tissues swell with inflammatory effusion. The pustules still increase in size, and the surrounding inflammation still augments, down to about the ninth day (eleventh day of the disease). The process of maturation, as it is called, is then completed. The above remarks apply more particularly to the eruption on the face ; on the lower part of the trunk, and on the extremities, its several stages occur somewhat later. The eruption of small-pox is always more abundant and close-set on the face and neck than elsewhere, and is generally, even in severe cases, scanty on the lower part of the trunk. When sparse the papules, like those of measles, often appear in crescentic groups ; but when they are more thickly clustered this arrangement is not observed. If the primary papules are much crowded, the pustules which result from them tend to coalesce, and thus to form extensive tracts of suppuration, in which the limits between the constituent pustules are scarcely or not at all distinguishable. When the pustules remain distinct from one another on the face, the attack of small-pox is termed *discrete* ; when they run together in the same situation, it is called *confluent*. The pustules of discrete small-pox are larger than those of the other variety, and the surrounding inflammatory areola is more obvious. The confluent form, however, is much the more severe, and attended with far greater subcutaneous œdema and ultimate destruction of tissue ; the face, and especially the eyelids, are apt to get enormously swollen ; and the hands are often so much enlarged and tense that the patient cannot close them. The variolous rash is not limited to the skin, but is generally developed also more or less abundantly on the mucous surface of the nose, mouth, fauces, and pharynx, and even on that of the larynx and trachea, and sometimes upon the conjunctivæ. The fully developed cuta-

neous pustules are circular in outline, unless altered in form by coalescence or other accidental circumstances, vary from  $\frac{1}{4}$  to  $\frac{1}{3}$  inch in diameter, are somewhat flat, and mostly depressed in the centre, or 'umbilicated.' In some cases their contents, even from an early stage, are mixed with blood; and not unfrequently they are associated with petechiæ and vibices.

In all cases of small-pox there is, on the first appearance of the rash, a sudden diminution of the severe symptoms which characterised the invasion; the temperature falls, and becomes in some cases nearly normal, the pulse lessens in frequency, the vomiting ceases, the febrile pains and pains in the back subside, delirium and other nervous symptoms disappear, appetite perhaps returns, and the patient seems to be convalescent. At the same time, however, the cutaneous eruption is producing some inconvenience; and he begins to complain of soreness in the mouth and tongue, with ptialism, and his throat gets painful, his voice hoarse, and a ringing or metallic cough probably comes on—phenomena which are due to the involvement in the rash of the mucous surface of the upper parts of the respiratory and alimentary tracts. The degree in which the symptoms of invasion subside, and the duration of the period of their abeyance, depend on the severity of the attack. In very mild cases the pocks, at the period at which they usually suppurate, begin to contract and dry up, and there may then be no interruption to the favourable progress of convalescence. In cases of medium severity the period of apparent convalescence continues up to the sixth or seventh day of the rash (eighth or ninth of the disease), at which time the maturation of the pustules commences. It is then interrupted by a sudden recurrence of febrile symptoms, which last for some three or four days, or until about the completion of maturation. This is the period of secondary fever, and is marked by chills or rigors, increase of temperature (which may even surpass that of the period of invasion), acceleration of pulse, dry furred tongue, and delirium. When the disease is of the confluent kind, the remission of symptoms at the commencement of the eruptive stage is very slight; the temperature may, perhaps, sink a degree, and there may be some slight general amelioration for four-and-twenty hours, or less; after which the febrile symptoms and delirium increase with the progress of the eruption, attaining their maximum severity, without any particular change in quality, during the period of maturation. It is in such cases that the swelling of the face, hands, and feet is greatest, that salivation is most profuse, that other symptoms referrible to the mouth and throat are most violent, and that delirium is most continuous. There are generally also, in these cases, tremulousness, subsultus, want of control over the evacuations, and extreme prostration; and not unfrequently diarrhœa occurs.

After the completion of pustulation, and at the end of the secondary fever, which events are generally nearly simultaneous, a period of very uncertain duration and of very variable phenomena, during which the pustules dry up and disappear, comes on. During the first three or four days, that is from the eighth or ninth up to the eleventh or twelfth day

of the eruption, the pustules ooze or dry up, dark-coloured, thick, adherent scabs form, and the skin begins to exhale a characteristic fetid odour—the cutaneous inflammation at the same time rapidly subsiding. The separation of the scabs usually takes place during the third week of the disease; but the healing of all the sores may not be completed for a week or two more, being preceded by the formation and detachment of successive crops of scabs. If the case be going on favourably, the febrile symptoms rapidly subside, the functions of the various organs are restored, the appetite returns, and convalescence is established. But it is during this period that many of the serious complications and sequelæ of small-pox manifest themselves, and delay the patient's recovery, or carry him off. These are most frequent after confluent small-pox, but may supervene on the milder forms. The following list comprises the chief of them. During the third or fourth week boils are apt to appear on different parts of the surface; and then, though more generally later, subcutaneous and even deep-seated abscesses often form rapidly, attain a large size, and are long in healing. Erysipelas, more especially of the face and head, is not uncommon; and gangrene, or pyæmia, occasionally supervenes. Pustules sometimes form on the conjunctivæ; and from these or other causes ophthalmia is apt to ensue, which may be suppurative and end in ulceration or sloughing, and perforation of the cornea. Otitis is sometimes observed. Of internal complications, the most serious are suppurative pleurisy, pneumonia, and bronchitis. Inflammation or œdema of the larynx may also be fatal about this time; but this event is chiefly to be feared during the period of secondary fever.

The eruption of small-pox generally leads to more or less destruction of the cutis vera, and the formation of indelible cicatrices. In some cases (especially of the discrete variety) only a few scattered pits may result. But in the confluent disease the destruction, especially on the face, is often most extensive, and the patient recovers, pitted, seamed, and scarred in all directions.

The description of small-pox just given is so full that we shall now, instead of discussing at length the groups of symptoms referrible to the various systems and organs, merely supplement it by adding certain details, which either have been omitted from it, or only slightly touched upon, or are of special importance.

The temperature, during the stage of invasion, usually rises rapidly to  $104^{\circ}$ , or even as high as  $106.5^{\circ}$ ; during the early period of eruption it falls several degrees, but for the most part remains distinctly febrile; at the period of maturation the temperature again rises, in mild cases to  $102^{\circ}$  or  $103^{\circ}$ , in more severe cases to  $104^{\circ}$ , and when a fatal result threatens to  $107^{\circ}$ , or even beyond this. Dr. Herman<sup>1</sup> has published an average or composite chart of the temperature of small-pox unmodified by vaccination, deduced from the actual charts of 31 unmodified and non-fatal cases of the disease. This chart, which represents the morning,

<sup>1</sup> *Med.-Chir. Trans.*, vol. lxvii.

afternoon, and evening temperatures from the third to the twenty-first day, may be regarded as typical.

FIG. 36. AVERAGE, OR "COMPOSITE," CHART OF SMALL-POX.

The pulse is quickened, especially during the periods of primary and secondary fever, but otherwise presents no special peculiarity. The respirations also are accelerated in relation with the amount of febrile disturbance, and, under conditions of great prostration and danger, become shallow and suspicious. Vomiting is a characteristic symptom of the period of invasion, and anorexia with thirst of the whole duration of the malady. In adults the bowels are generally constipated, and the occurrence of diarrhœa during the development of the rash is an unfavourable symptom. In children, however, diarrhœa is a common, and on the whole a favourable sign, both in the period of invasion and subsequently. Salivation is almost invariable in confluent cases; comparatively rare and ill-marked in mild cases.

The urine presents the ordinary febrile characters; and in some cases (about one-third of the total number) contains albumen, with casts and occasionally blood-corpuscles. Albuminuria appears early in the disease, and may continue to the end; but it rarely, if ever, leads to permanent mischief or to anasarca. According to Mr. Marson, suppression never occurs. Inflammation of the ovary or testicle is occasionally observed during the eruptive stage. Perspirations are usual in discrete variola from the beginning of the disease up to its termination; but they are generally absent in confluent cases, and are not common in children. According to the older authors, and also according to Trousseau, the swelling of the hands and feet which takes place in confluent small-pox during the period of maturation is a favourable sign.

The invasion-period, in children, is often marked by drowsiness, and coma and convulsions are not unfrequent; in adults there is more or less giddiness and dulness, and convulsions occasionally arise even in them; there is also frequently, and especially in severe cases, maniacal, busy, or muttering delirium. In confluent cases the delirium may continue during the early period of efflorescence, and it generally reappears or becomes more severe at the time of the secondary fever. At this time, too, the patient is liable to outbreaks of violent mania. Tremulousness of muscles, subsultus, and picking at the bed-clothes, occur in the worst cases. The

pain in the back, which is so characteristic of the onset of the disease, appears to be spinal, and is often associated with temporary paraplegia and loss of control over the bladder and rectum.

Many varieties of small-pox have been enumerated. Exceedingly mild cases are sometimes observed, in which the period of invasion is well marked, but in which no appearance of rash follows, or a few scattered pocks only are discovered on the skin or mucous membrane. Other exceptionally mild cases are met with, in which the disease begins with all the symptoms that usher in a well-marked attack of the disease; in which the pocks appear numerous yet discrete; but in which, at the period when suppuration should take place, the vesicles dry up. In both of these cases there is no secondary fever, and the patient rapidly convalesces. The most important forms of natural small-pox, however, are those which are known respectively by the names of 'discrete,' 'confluent,' and 'malignant' small-pox. In the *discrete* form the invasion-phenomena are generally well pronounced; but the subsidence of febrile symptoms on the first appearance of the rash, and their abeyance until the commencement of suppuration, are constant; the secondary fever, too, is generally slight; and the patient for the most part recovers without any complication. Nevertheless, in discrete small-pox there is some danger of death on the eighth or ninth day of the disease, from the sudden accession of cerebral symptoms, especially of coma. In the *confluent* variety, the symptoms are at all stages far more severe than in the discrete form; especially, there is little and very temporary remission of febrile symptoms; and, moreover, phenomena which are rare or absent in the latter and have already been considered assume considerable prominence here. It is in this variety, too, that complications and sequelæ are specially liable to come on. Death from confluent small-pox usually occurs from the tenth to the fifteenth day of the disease, and is due for the most part to a combination of coma and asthenia. But it may also supervene during the next month or two from the effects of sequelæ. *Malignant small-pox* is characterised especially by the early appearance of petechiæ and vibices, hemorrhagic effusion into the pocks and conjunctivæ, discharges of blood from the various orifices, and rapid collapse. The symptoms of invasion are usually intense, the patient looks from the first as if struck down by a mortal disease, and often dies on the fourth or fifth day, or before the eruption has had time to become distinct. Occasionally, indeed, the patient dies collapsed on the third day, before the appearance of the eruption, but possibly presenting chemosis, together with a few petechial spots about the lower part of the abdomen. There may be delirium, but the patient often remains conscious to the last.

Small-pox occurring after vaccination is generally modified in character, and is termed *modified small-pox*, or sometimes, and inappropriately, *varioid*. It commences with all the usual symptoms of small-pox, and may assume the characters of the discrete, confluent, or even malignant form; but about the time when the tissues around the pustules should inflame and swell and secondary fever be established, or even before that

period, the eruption begins to dry up, and the febrile symptoms subside or present only very slight and transient exacerbation. Trousseau says that delirium is more common in modified than in natural small-pox, but is less serious, and that salivation rarely occurs in the modified confluent affection. It need scarcely be added that the degree of modification varies; that the attacks, though generally benign, are sometimes serious; and further, that those occurring, even after successful vaccination, sometimes do not deviate appreciably from the natural disease.

Modified small-pox is for the most part a mild disease, and rarely fatal. Natural small-pox, on the other hand, is fatal in a very high degree. The statistics of the Small-pox Hospital for twenty years show, that of those patients who had previously been vaccinated the mortality was at the rate of 6.56 per cent.; and that of those who had good vaccine cicatrices only 2.52 per cent. died. It is very different, however, as regards unmodified small-pox, which destroyed 37 per cent., or more than one-third of the total number attacked. Discrete small-pox was attended with a mortality of 4 per cent., semi-confluent with a mortality of 8 per cent., and confluent with a mortality of no less than 50 per cent. Statistics from the same hospital show that the mortality among patients under five years of age was 50 per cent., and among those upwards of thirty still higher. The lowest rate of mortality was between five and twenty. According to Trousseau children under one year never recover from small-pox (a statement, however, which is not absolutely true), those between one and two rarely. Mr. Marson states that persons above sixty also almost invariably succumb. Pregnant women usually abort and die. They do, however, occasionally recover, whether abortion takes place or not.

We may here call attention to a remarkable group of nervous sequelæ of small-pox, to which Westphal first drew attention in 1871, and of which a few examples have been recorded since. The subject has been ably treated by Jaccoud, and in a paper read before the Clinical Society by Drs. Whipham and Myers. It appears that in occasional cases, for the most part attended in the eruptive stage with pronounced nervous symptoms, the patients become affected, even during this period, with paralytic weakness of the limbs and difficulty in articulation; and that these phenomena, though tending to subside, continue for years, or even permanently. The affection of speech, which is the most striking symptom, concerns articulation only, and is marked by exaggeration of movements of lips and tongue, divided utterance and monotony of tone. It is, in fact, exactly like the speech described further on as occurring in ataxic patients. The arms are somewhat weak, and the movements of the hands clumsy. The legs also are weak, and there is unsteadiness of gait, with some increase of the tendon reflexes. There is generally some emotional disturbance; but intelligence, excepting while the fever lasts, is unaffected. The symptoms are not unlike those of some forms of disseminated sclerosis; but the prognosis is much more favourable.

*Morbid anatomy.*—The post-mortem examination of small-pox cases

reveals but little beyond what has been already described. In most cases the blood is dark and imperfectly coagulated; although, in the ventricles of the heart, fibrinous clots may be discovered. In the malignant form of the disease, extravasations of blood may be found beneath all the serous and mucous surfaces. Generally the heart is flabby, the liver pale and soft, and the spleen pulpy. The tongue presents a thick fur, which may be detached at the edges and elsewhere in patches. And the palate, fauces, nasal fossæ, larynx, trachea, and bronchial tubes, and even the œsophagus, may be found more or less deeply congested, and covered with a granular film due to increase and softening of the epithelial layer; and may present, in addition, numerous excoriations which from their size and distribution are suggestive of their origin in the small-pox rash. Under such circumstances, the bronchial tubes are loaded with muco-purulent fluid, and the lungs are congested and œdematous, and possibly pneumonic. As regards the skin-eruption, we may here add a few details which were out of place in a clinical account of the disease. The papules are due partly to the punctiform hyperæmia and germination of the cutis, partly to swelling, mucous degeneration and vacuolation of the cells of the rete mucosum. The central vacuolated cells of the thickened rete presently rupture, and unite to form an irregular anfractuous cavity. Into this central cavity, and into the surrounding vacuoles, serum exudes from the subjacent vessels, together with abundant leucocytes, and often a greater or smaller number of red blood-discs. By the continuance of these processes the pock enlarges in area and becomes purulent: its superficial wall being formed by the horny layer of the epidermis, its deeper wall by the surface of the corium, and its cavity, even to the last, presenting a multilocular or anfractuous character. The umbilicated form of the pock appears to be connected with its mode of development, and to be due to the fact, that while it extends peripherally its centre remains crossed by bands and filaments. The suppurative process need not implicate the true skin below; but not unfrequently it involves and destroys it to a greater or less depth, and is prolonged inwards along the hairs or glands. Under the former circumstances the pustule leaves no permanent trace; under the latter a depressed cicatrix results, presenting numerous pits upon its surface.

*Treatment.*—In the mildest forms of small-pox medicinal treatment is scarcely called for; in the severest it is useless; and indeed, under any circumstances, it has but little influence over the course of the disease. The patient should be placed in an airy chamber, which should be well ventilated, and kept at a uniform and medium temperature. He may take as medicine some cooling drink—lemonade, soda-water, or other saline or acidulated solution. If the bowels be confined, they may be acted upon by some mild laxative; if there be diarrhœa (especially in adults), they must be restrained by opium or other astringents. The soreness of the throat may be relieved by warm bland drinks, or black-currant jelly; and if there be much discharge from the nose and about the fauces, these parts may be washed with some mild detergent or

astringent solution. Opium is often of value both in relieving the delirium and in assuaging the pain of the invasion period; but it is especially useful during the period of secondary fever. If there be great tendency to collapse, ammonia may be serviceable. Nourishment should be regularly administered, and should consist of the materials generally suitable for febrile conditions, namely, milk, rice-water, gruel, beef-tea, and such like. Alcoholic stimulants must be given according to circumstances, but are especially important in the malignant form of the disease, and in the later periods of confluent small-pox, or whenever there is tendency to collapse. As to local treatment, the patient should be kept clean and frequently sponged with tepid water; and, as the eruption reaches its height, and in its decline, the eyes and various mucous orifices need especial care. They should be sponged and dried, and anointed with olive oil; and if there be any tendency to conjunctival inflammation and ulceration, weak solutions of nitrate of silver or sulphate of zinc should occasionally be dropped into the eyes. Various plans have been suggested and employed to prevent pitting; but it is questionable if any are really efficacious. It has been recommended to puncture the pustules, to wash away their contents, and then to insert into each a fine point of nitrate of silver. If this be done, it should be when the pocks first distinctly contain fluid; but the plan is scarcely applicable to the cases in which the prevention of pitting is most needed, namely, confluent cases. The local application of strong carbolic acid has also been recommended. It is probably best, generally, to anoint the surface with carbolised oil. During the period of decline of the eruption, and that of convalescence, the strength of the patient needs to be supported in every way, by good diet, by stimulants, and by quinine or other tonics. The various complications of small-pox must be treated according to ordinary principles, bearing in mind, however, that their presence as a rule enfeebles the patient, and is therefore an indication for sustaining strength.

But the most important treatment of small-pox is the preventive, by means of inoculation with the small-pox virus, or that of cow-pox. The former plan has fallen into disuse, and is now penal in this country, yet no doubt under certain conditions it might be revived with advantage. The inoculated small-pox is a much milder disease than that contracted in the usual way; and, according to Dr. Gregory's analysis of the records of the Small-pox and Inoculation Hospital of London, from the year 1746 to 1822, the deaths from it were at the rate of only three in a thousand. The mildness of the inoculated disease appears to be promoted by using the virus from a mild case, and by repeated selection of inoculated cases for the purposes of inoculation. It may be further promoted by inoculating those only who are at the age at which small-pox is least dangerous to life. The virus should be taken from a pock which has not yet begun to suppurate; and the operation of inoculation should be performed exactly like that of vaccination. Our remarks on vaccination will be given in the next article.

IX. COW-POX (*Vaccinia*). VACCINATION

*Definition.*—A contagious disease of cattle, characterised by the local development of pustules (almost exactly resembling in their progress and results the pocks of variola), and communicable by inoculation.

*Causation and relations with Small-pox.*—Cow-pox has been found to prevail epidemically at times in every country in Europe. Yet, although thus common, it is doubtful if it is communicable from animal to animal either by the breath or by the secretions. It is certain, however, that it is eminently contagious by inoculation from its specific pocks. Like most other affections originating from contagion, cow-pox by one attack protects against future attacks, but it similarly confers immunity against attacks of small-pox. It is this fact which gives so great an interest to all questions relating to its intimate pathology, and especially to the question of its exact relations with small-pox. Its identity with the latter disease was early surmised; and many arguments, in addition to the fact that it is protective against it, have been adduced in favour of this view. Thus, there is scarcely any appreciable difference between the pocks of the two affections, either in their anatomical characters or in their progress; it has been over and over again observed that epidemics of small-pox and cow-pox occur in relation to one another; and it is certain that since the introduction of vaccination the so-called 'natural' cow-pox has in great measure disappeared. But far more important than such facts as these are the experimental proofs which have been obtained by Messrs. Ceely and Badcock, and some foreign observers. They have inoculated cows with small-pox lymph; have succeeded by this means in producing pustules at the seat of inoculation exactly like those of cow-pox; and with their contents have successfully imparted cow-pox to healthy cattle, and to the human being an affection exactly like that induced by ordinary vaccination. Further, by lymph thus obtained many years ago from bovine small-pox successful human vaccination has been perpetuated down to the present time. As confirmatory of this view of the relation between small-pox and cow-pox, it may be pointed out that natural cow-pox occurs only in the teats and udders of *cows*—that is, in exactly the situations in which small-pox would be most likely to be given to them by inoculation from man; and also that cow-pox when experimentally inoculated from cow to cow, instead of being perpetuated, as it is in man, tends before long to die out. It seems clear, therefore, that cow-pox is small-pox, modified and deprived of its virulence by transmission through the cow.

*Symptoms and progress in cattle.*—Natural cow-pox affects chiefly the udders and teats of cows, and is indicated in them by the development of a number of pustules which individually run through all the stages characterising the small-pox pustule. They begin as papules, in a few days become vesicular, and by the seventh, eighth, or ninth day attain

their full development, measuring then from  $\frac{1}{2}$  inch to  $\frac{3}{4}$  inch in diameter. From that date the contents become purulent, and a congested areola, with much subcutaneous induration and thickening, forms. A thick dark adherent scab is developed by about the thirteenth or fourteenth day, which gets detached in the course of the following week, leaving a depressed cicatrix. The febrile symptoms which attend the progress of the disease are very slight, and for the most part of no importance; generally, moreover, the local affection is quite free from untoward complications. When cow-pox is given by inoculation, the papules as a rule first make their appearance at the end of three days; occasionally, however, on the second or the fourth day.

*Symptoms and progress in man.*—Cow-pox as it affects the human subject differs but little from the same disease in cows. No specific change is observable at the point of inoculation until the end of the second day, or the third day, when a small congested papule makes its appearance. This gradually increases in size, and on the fifth or sixth day has become a circular greyish vesicle, with a somewhat depressed centre. By the eighth day it has attained its full development—forming then a well-marked prominent greyish vesicle, with a flat or cupped surface, and containing in its interior a colourless, transparent, viscid fluid. On the eighth or ninth day the contents of the vesicle begin to get purulent, a red areola forms, and thickening and induration of the inflamed area take place. These phenomena increase during the next two days; the induration and thickening become greater and more extensive, the areola attains a diameter of from one to three inches, the pock itself undergoes some little extension, and its contents get wholly converted into pus. After the tenth or eleventh day the pustule begins to dry up, and the areola and other signs of inflammation to subside. By the fourteenth or fifteenth day a hard dark-coloured scab has formed, which contracts and blackens, and from the twentieth to the twenty-fifth day falls off, leaving a depressed pitted permanent scar.

The vaccinated patient does not usually present general symptoms or complications until about the eighth day, and during the two or three days immediately following. There is generally then some febrile disturbance, with restlessness, irritability, and slight derangement of the digestive organs; the glands next above the seat of operation usually get enlarged and painful; and sometimes a roseolous rash spreads over the vaccinated limb, and thence maybe to other parts of the body. This rash is sometimes vesicular or papular.

The consequences of vaccination direct from the cow are identical with those of vaccination with humanised lymph; occasionally, however, there is a little difficulty in imparting the disease, and the eruption in some cases is somewhat retarded.

In cases of revaccination one of three results will follow: if the patient be fully protected, it produces no effect beyond a little local irritation due to the lancet-puncture and the introduction of irritant matter; if all protection have ceased, the operation is followed by the development of the

typical pock ; if there be simply impairment of protection, the results of the operation are modified. In the last case, the local effect comes on early, the papule (which may remain a papule or become an acuminate vesicle) attains its full development on the fifth or sixth day, and immediately after forms a scab which falls off in the course of a day or two ; but there is generally a good deal of attendant local and constitutional irritation—much more, in fact, than occurs in primary vaccination.

Other circumstances besides those which have been considered occasionally modify the results of vaccination—among them, the age of the pock from which the lymph has been taken, and the health of the patient operated upon.

It must not be forgotten that cow-pox, whether in the cow or in man, is not comprised within its local manifestations ; but that (however mild its attack may be) it is a disease involving the whole organism, as is proved by the marvellous influence which one attack has in protecting the body from subsequent attacks both of cow-pox and of small-pox, by whatever route and in whatever manner they may be introduced. Guided by what we know of inoculated small-pox (namely, that at the seat of inoculation a papule appears, which gradually becomes a well-developed pock ; that this is simply a local affection, which is followed about the eighth day by feverishness and other symptoms of invasion, and in two or three days more by the general eruption), it seems obvious to assume that the pustules of cow-pox which appear on the udders of cows, and those which result from vaccination on the arms of men, are simply, as they appear to be, local affections, on which the true generalised disease (in this case abortive and altogether trivial in its symptoms) supervenes at about the period of maturation : in other words, that the period which elapses between inoculation and the full development of the pock corresponds strictly to the latent period of other exanthems.

*Protective influence of Vaccination against Small-pox.*—A belief in the protective influence of cow-pox against variola seems to have been commonly entertained in Gloucestershire during the latter half of the eighteenth century. And a similar belief appears to have prevailed about the same time in some parts of Germany. It is said, indeed, that a schoolmaster, named Plett, in Holstein, vaccinated two children in the year 1771 ; and it seems to be established that an English farmer, named Benjamin Jesty, performed the same operation on his wife and two sons in the year 1774. The value of vaccination was, however, first established on a solid basis by the scientific investigations of Edward Jenner, whose attention was directed to the subject while he was yet an apprentice, and whose first publication in reference to it appeared in the year 1798. We need not pursue in detail the further history of vaccination. It is sufficient to say that its practice has been adopted since then throughout the whole civilised world ; that the claim which Jenner originally made for it (namely, that it is as protective against subsequent attacks of small-pox as an attack of small-pox itself is, and neither more nor less so) has been verified by universal experience ; that experience and experiment alike

have shown that its protective influence is in no degree diminished by its continued transmission from man to man ; and, lastly, that small-pox has died out or diminished in severity in exact proportion as efficient vaccination has been generalised. It is certain, indeed, that thorough vaccinal inoculation confers in most cases absolute exemption for life ; but that in some cases the protective influence diminishes in the course of years, so that if the patient contracts small-pox, he has it in a modified and mild form ; and that where small-pox has been rife, or epidemics have prevailed, the unwonted occurrence of the disease has been distinctly traced to neglect of vaccination, or to imperfect vaccination, or to both. Mr. Marson's tabulated results of the experience at the Highgate Small-pox Hospital during twenty years show at a glance the accuracy of the above statements :—

Patients admitted with small-pox		Number admitted	Mortality per cent.
1.	Having one vaccine cicatrix . . .	2,001	7·73
2.	„ two „ cicatrices . . .	1,446	4·70
3.	„ three „ „ . . .	518	1·95
4.	„ four or more „ . . .	544	0·55
5.	Stated to have been vaccinated, but having no cicatrix . }	370	23·57

It will be recollected that the mortality of primary small-pox is shown, by the same authority, to be 37 per cent. Dr. Gayton's more recent analysis of 10,403 cases of small-pox coming under his personal observation in the Small-pox Hospitals of the Metropolitan Asylums Board substantially confirms Mr. Marson's conclusions.

*Dangers of vaccination.*—The only valid objection to vaccination is that it may, and occasionally does, induce or introduce maladies which the patient would otherwise have escaped. We do not here refer to the immediate accidental results of vaccination, such as erysipelas and pyæmia, which may equally follow on a mere prick or the simplest scratch, but to certain constitutional disorders, such as scrofula and syphilis, which have been attributed to it. There is no doubt that syphilis has been thus imparted ; but the recorded cases are marvellously few, and these have been the result of gross carelessness or ignorance ; for there is little reason to believe that a vaccinated child, who presents no visible indications of syphilis, could impart that disease, and it is certain that the pure lymph of a distinctly syphilitic child is not necessarily charged with the syphilitic virus. As regards scrofula, the only ground for assuming its inoculability by vaccination is the circumstance that lichen, eczema, and impetigo (affections which are common in children, especially about the period of teething, and by some erroneously regarded as scrofulous) occasionally supervene on vaccination, as they do on other forms of local irritation.

*Performance of vaccination.*—The operation of vaccination should be performed at as early a period of life as possible, especially if small-pox has been in any degree prevalent. It is now required by law that a child shall

be vaccinated within three months of birth. It is desirable that it should be in good health, and free from skin-disease. In order to obviate the tendency which the vaccinal influence has to die out, it is now almost universally held that the operation ought to be repeated about the period of puberty. And, further, it is always important, in the case of persons who are, or are liable to be, exposed to small-pox (especially if they have only imperfect vaccinal marks and have not been successfully revaccinated), that the operation should be at once repeated. But it should be borne in mind that vaccination has no modifying effect on small-pox which has been previously contracted, unless it be so timed that the maturation of the vaccine vesicle shall precede the period of the variolous invasion. Thus, since the primary vaccine vesicle attains its full development on the ninth or tenth day, and the latent period of small-pox is usually twelve days, primary vaccination, to have any beneficial effect, should be performed certainly not later than the second or third day after exposure to the variolous contagion. The vesicle, however, which follows revaccination attains its maximum on the seventh or eighth day; so that if the patient has been previously vaccinated, the operation may possibly be beneficially performed as late as the fourth or fifth day after exposure.

The lymph for vaccination should never be taken from persons who are diseased, or in whom there is any suspicion of syphilis or other infectious disorder; nor from pocks which are ill-developed or purulent; nor from those which are the product of revaccination. Good vaccine lymph is yielded by normal pocks from the fourth or fifth to the eighth day after inoculation. Lymph of a later date should never be employed. As a rule it is taken on the eighth day. The vesicles should be freely punctured with the point of a lancet, care being taken to avoid hemorrhage; and the fluid which exudes should then at once be employed for vaccination, or should be preserved on ivory points which may be dipped into it, or between glasses, or preferably in capillary glass tubes. No squeezing of the vesicle should be had recourse to; but if, after all the lymph which first flows has been used, the surface be gently wiped, a fresh exudation of good lymph usually takes place. Lymph may also be diluted with glycerine, in the proportion of from one to two parts of glycerine to one of lymph, and thus preserved—a method of great value when lymph is scarce.

Vaccination is generally, and certainly most conveniently, performed on the upper and outer part of the upper arm. There, four or five distinct punctures should be made at  $\frac{1}{2}$  or  $\frac{3}{4}$  inch distance from one another. Various modes of performing the operation are recommended. The simplest is to make with a sharp, clean, well-charged lancet, in the stretched skin, a valvular puncture directed from above downwards, and sufficiently deep to wound the vessels of the cutis. A second method, of which there are numerous modifications, is to make groups of parallel or crossed scratches, or fine punctures, so as to allow of a little oozing of blood, and then having wiped the blood away to anoint the surface with the vaccine lymph. If the groups be small they should be five in number; if large, three will

suffice. If the lymph which is employed be fresh, or have been preserved in capillary tubes, it may at once be applied on the point of the lancet; but if it have been preserved in the dry condition, it is essential that it be first moistened thoroughly with a small quantity of water. If no result whatever follow the operation, whether it be in a case of primary vaccination or in one of revaccination, either the lymph employed is inefficient, or the operation has been imperfectly performed, or (what is less probable) the patient is insusceptible. Under any circumstances the operation should be repeated until a definite local result of some kind or other is obtained.

---

## X. CHICKEN-POX (*Varicella*)

*Definition.*—A specific contagious disorder, characterised by the appearance of vesicles in successive crops, which in the course of two or three days form scabs.

*Causation.*—Varicella has been largely confounded with small-pox, of which it has been regarded as a modified variety. This view was entertained even by Hebra. Of the perfect distinction, however, between them there can be no doubt; for the one disease is not protective against the other, although each is protective against its own future attacks; the one disease never imparts the other; and they occur in independent epidemics. Chicken-pox is contagious in a high degree, and spreads both by means of the air and through the medium of fomites. It is doubtful whether it has hitherto been imparted by inoculation. It occurs epidemically; but its epidemics seem to be neither so frequent nor so widespread as those of measles, whooping-cough, and scarlet fever. It attacks children mainly, yet adults are by no means exempt.

*Symptoms and progress.*—The period of incubation is somewhat uncertain. According to different authors, it varies between four or five and sixteen or seventeen days. In some cases this stage is of exactly a week's duration, but more commonly perhaps it lasts a fortnight. The invasion is marked by febrile symptoms, which are occasionally severe but present no distinctive character, and which, generally in a few hours, at all events before the completion of twenty-four, are followed by the appearance of the rash. This consists in the first instance of a number of rosy papules, not unlike the spots of typhoid fever, appearing singly, or in groups of two or three, on various parts of the body (head, face, trunk, limbs), but most commonly, perhaps, first upon the chest. These in the course of a short time, even after a few hours, become distinct vesicles, containing a transparent fluid, and usually surrounded by an inflammatory halo. The vesicles, which are at first small and rounded or acuminate, increase in size for a day or two, becoming sometimes as large as a split pea, occasionally irregular in form, and often umbilicated: their contents at the same time get milky. They then rupture or dry up, and small dark-

coloured adherent scabs result. The formation of the scabs is completed at the end of four or five days or a week from the first sign of illness, and they may remain adherent for two or three days or even a week longer, when they separate, leaving red stains which are slow to disappear, and not unfrequently permanent depressed cicatrices. The eruption is not limited, however, to the generally scanty crop which first appears. But during the first three or four days of the disease fresh crops of papules in largely increased numbers, and irregularly distributed, spring up day by day, and these go through the same stages as those which were first developed. During the progress of the disease vesicles with inflamed areolæ usually appear, in small numbers, on the palate, sides of the tongue, and mucous surface of the lips and cheeks.

The general symptoms of varicella are for the most part slight and unimportant. There is commonly some feverishness, languor, and loss of appetite; and the fever is liable to nocturnal exacerbations during the maturation of the vesicles. The temperature often rises to  $101^{\circ}$ , and may reach  $104^{\circ}$ . The tongue probably remains clean throughout. Occasionally, the symptoms are much more severe, though never probably so severe as to excite serious alarm. Death rarely if ever results.

The malady usually attains its height in a week or ten days, and runs its course in ten days or a fortnight. The complications and sequelæ are unimportant; nevertheless, children often remain weak and out of health for some time after an attack.

*Treatment.*—The patient should be separated from those who are liable to take the disease, and confined to his room, if not to bed. He should be prevented, if possible, from scratching his pimples, those at least upon the face, in order to diminish the liability to pit. No further special treatment is necessary.

## XI. TYPHUS

*Definition.*—A highly contagious fever, lasting from two to three weeks, and attended with a characteristic measly eruption coming out from the fourth to the seventh day.

*Causation and history.*—Typhus fever seems to be a disease especially of temperate climates. No European country is free from its occasional epidemic prevalence, but from Ireland it is probably never entirely absent; and indeed Great Britain and Ireland may be regarded as its headquarters. Epidemics have occurred in the United States and in Canada. There is even now some doubt as to whether it has ever been observed in India; but, excepting this doubtful case, it is quite unknown in tropical countries. It has been introduced into Australia and New Zealand, but has not spread there. Typhus appears, for the most part, in casual outbreaks which assume an epidemic character, spread widely, and after lasting for months or years subside and die out. Almost all recorded

epidemics seem to have been traced to long-continued overcrowding, in association with defective ventilation and personal filth. With these conditions starvation no doubt is often to a large extent combined. But starvation alone, such as results from famine or widespread want (from whatever cause) of the necessities of life, leads to the development rather of relapsing fever than of typhus; while, on the other hand, typhus has not unfrequently become epidemic where there has been no starvation, but where the other conditions enumerated have prevailed in a marked degree. Epidemics of typhus have originated mainly in the overcrowded parts of great cities, during seasons of distress and want and consequent exceptional overcrowding; in armies, under equivalent conditions; and in prisons. There can be no doubt, indeed, that overcrowding and bad ventilation are most effective agents in concentrating the typhus poison, and in promoting the spread of the disease; and it may be added, that anything which depresses body or mind (want of food, fatigue, intoxication, fear, anxiety, perhaps even the debility of convalescence) must be regarded as a predisposing cause. In the countries in which typhus chiefly occurs, season and weather appear to exert no direct influence over its origin or spread. All ages are liable to its attacks, although it is shown by statistics to be most common between fifteen and twenty-five; and males and females suffer from it in nearly equal proportion. One attack confers almost complete immunity against subsequent attacks; yet, occasionally, two and even three seizures have been observed in the same individual. Excepting those who have thus acquired protection, everyone is liable to take typhus. It is true that some unprotected persons even when exposed daily to the influence of the disease, fail to contract it; but many cases are on record where such persons, after years of immunity, have been attacked with it at last and have then succumbed to the attack.

That typhus is a highly contagious disease is established by overwhelming evidence. Its poison is carried by the atmosphere, and is absorbed and retained in a potent condition for a considerable time by fomites. But it presents certain marked peculiarities of behaviour external to the system; thus it clings, as it were, around the body of the patient, and seems to be rapidly destroyed by diffusion through the atmosphere; so that while its operation is intense under appropriate conditions of overcrowding and bad ventilation, it is almost *nil* under opposite circumstances; and hence the disease rarely spreads (excepting to the immediate attendants) in the wards of a well-arranged hospital, or among the households of the middle and upper classes. The contagium of typhus is probably exhaled with the breath and from the general surface. It is doubtful, however, whether the other excretions are infective, or whether the disease can be imparted by the dead body. Both the breath and the sweat of typhus patients yield a characteristic offensive odour, and there is reason to believe that the contagiousness of a case has some direct proportion to its smell. Dr. Murchison considers that the disease is most contagious from the end of the first week up to convalescence.

Although it is now admitted by all the best observers that typhus when once it has made its appearance is eminently contagious, it is still a question whether typhus epidemics owe their origin to new developments of the typhus poison, or are due to the presence in a latent form of the contagium, which is rendered operative by the concurrence of suitable conditions. The latter view is doubtless the true one.

*Symptoms and progress.*—The latent period of typhus appears to be of very uncertain duration. Cases are recorded in which the symptoms of invasion manifested themselves almost immediately after exposure to the concentrated poison. On the other hand, the primary symptoms have in some cases failed to appear until after the lapse of twenty-one days, or even more. The usual period varies probably between five or six and twelve or fourteen days. The invasion is occasionally heralded by an ill-defined sense of poorliness lasting for a day or two; at the end of which time, or much more commonly without any such warning, the initial symptoms manifest themselves. These generally consist in a sense of chilliness or slight rigors, pain in the forehead and back, and soreness in the thighs and other fleshy parts of the limbs; with which are associated before long, or from the commencement, increased heat of skin, occasional slight sweats, diffused dusky redness of face and congestion of conjunctivæ, acceleration of pulse, furring of tongue, anorexia and thirst, scanty and high-coloured urine, muscular weakness, lassitude, giddiness, and loss of sleep, or disturbed sleep with tendency to dream. Occasionally there is some nausea or even sickness, and generally the bowels are constipated. For the first two or three days, notwithstanding gradual aggravation of his symptoms, the patient may not feel sufficiently ill to take to his bed. From the third to the seventh day (generally on the fourth or fifth) the characteristic measly eruption makes its appearance on the sides of the chest and abdomen, and on the backs of the hands, wrists, and elbows, and in the course of a couple of days becomes general over the trunk, arms, and legs, and sometimes, but much more rarely, shows itself on the neck and face. It remains out, well developed but undergoing slight changes of colour, for two or three days more, then gradually fades, and finally disappears by about the fourteenth day, unless it assumes a petechial form, when its disappearance is retarded. About the time when the eruption commences, or a little earlier, the patient has probably taken to his bed, and has begun to be apathetic and forgetful, to present a dull and listless expression, and to ramble at night. Presently he loses his headache, becoming, however, increasingly dull, forgetful, and stupid; and the delirium, which had hitherto been nocturnal and probably limited to the moments between waking and sleeping, becomes constant. Occasionally the delirium is violent and maniacal, and the patient requires constraint; sometimes it is the busy delirium of delirium tremens; but much more commonly it is of the low muttering kind, known by the name of 'typhomania,' into which, indeed, the other varieties tend soon to merge. In this condition the patient can at first be readily recalled to himself, and will answer correctly, and do what he is told to do. His

aspect becomes more oppressed ; the redness of his face and eyes, and his rash, assume a more dusky tint ; sordes begin to collect on his teeth, and his tongue becomes dry and brown ; his respirations and pulse increase in frequency, and the latter gets small, weak, and sometimes dicrotous or irregular ; his temperature falls somewhat ; his skin becomes clammy, his limbs tremulous ; and general debility increases rapidly. By about the tenth day the typhoid symptoms of the disease are fully developed ; the patient has become still feebler ; he lies in bed on his back with his mouth half open and his eyes half closed, taking no notice of what is going on around him ; he is in a semi-comatose condition, muttering at times unintelligibly and incoherently, breathing sometimes more rapidly, sometimes less rapidly, than natural, and probably moaning or groaning with each respiratory act ; his lips and teeth are coated with sordes, his tongue is small, hard, dry, and black ; he tends to sink towards the bottom of the bed ; his muscles are tremulous, and he has subsultus tendinum, especially in the arms, and floccitatio or a tendency to pick at the bed-clothes ; his motions are passed unconsciously, but his urine is generally retained, though dribbling away perhaps from the over-distended bladder ; his pulse has become extremely feeble, dicrotous, irregular ; his temperature probably still shows an inclination to sink ; the rash fades or becomes replaced by petechiæ : and perspirations break out. There is a tendency also to the formation of bed-sores.

These symptoms probably continue for several days, the patient meanwhile becoming more and more prostrate and comatose. And then, generally on or about the thirteenth or fourteenth day, either the coma becomes profound, the temperature rises rapidly, and the patient sinks ; or he falls into a gentle sleep, from which, after some hours, he awakes sensible and convalescent, with a greatly diminished temperature and pulse, but in a condition of extreme debility. If the case continues to go on favourably, the tongue cleans, the appetite returns, and restoration to perfect health ensues at the end of three or four weeks.

We will now discuss some of the more important phenomena of typhus *seriatim*. The temperature rises at once, and generally attains its maximum, which rarely exceeds  $106^{\circ}$  in adults and  $107^{\circ}$  in children, between the middle and end of the first week. Exceptionally it does not rise above  $103^{\circ}$ . It remains at its maximum for two or three days, and then (usually between the seventh and tenth day) falls slightly ; continuing to fall until the period of crisis, when, according as death or recovery takes place, there is either a rapid rise, which may exceed by several degrees that previously attained, or a sudden fall. The diurnal variations are slight and irregular, though on the whole tending to present an evening rise and a morning fall. If a high temperature be maintained or an unusual rise take place during the second or third week, some inflammatory complication is probably present.

The eruption of typhus embraces two factors, namely, a mere mottling of the surface, and distinct dusky-red spots. They are usually present together. The mottling, which soon becomes general, precedes the

development of the rash, and first appears in those situations in which the rash subsequently commences. It is due to the appearance of abundant ill-defined dusky patches which are not elevated, vanish on pressure, and individually are scarcely perceptible. The rash presents the colour and very much the aspect of that of measles. The spots, however, are smaller and less elevated, and do not assume a crescentic arrangement. They are slightly raised, roundish, fading at the margins, and at first disappear on pressure. For the first day or two their colour is comparatively bright, and due simply to stagnation of blood in the capillary vessels; during the subsequent two or three days they assume a dusky hue, the result probably in some degree of the transudation of the colouring matter of the blood; and then either they fade away, or hemorrhage takes place into them and they become converted into petechiæ. The typhus eruption is almost invariably present. In the year 1864 it was observed in the London Fever Hospital in 97·77 per cent. of the cases admitted. In children it is often very slight and of short duration, and may therefore be readily overlooked. In adults it is usually well developed, and generally the severity of the disease is in proportion to the abundance of the rash. The copious formation of petechiæ which often occurs towards the latter part of the second week is an unfavourable sign.

The respirations are generally slightly increased in number during the earlier period of the disease. In the typhoid stage they may rise to thirty or forty in the minute. From the beginning of the disease there is very often a slight cough, and this may continue throughout the illness; or it may increase and be attended with mucous expectoration which is sometimes tinged with blood. It is connected with the congestion of the bronchial tubes and lungs which so commonly attends typhus.

The action of the heart is weak, and towards the latter period of the disease the first sound often becomes inaudible. The pulse is always feeble and generally small, and its feebleness and smallness increase as the disease advances, until at length it becomes undulating, thready, irregular, and almost imperceptible. Its rate presents great variety. In adults it usually ranges between 100 and 120. During the first few days it rarely exceeds 100. Subsequently it rises in frequency, and it may reach 130 or 140 or more in the minute. But when it exceeds 120 the danger is generally very great. Occasionally it falls in the second week to 40 or 50. In children the pulse is usually much quicker than in adults.

Sickness is not a common feature of typhus, although it occasionally marks its onset. The bowels are generally constipated and the motions normal. But occasionally diarrhœa occurs early in the disease; and it is by no means uncommon about the period of the crisis, when also it may be dysenteric. The tongue at the beginning may be only abnormally red, or even natural; but it is soon covered with a thick whitish fur, which gradually gets yellowish, and towards the end of the first week brown. Later the tongue shrinks and becomes black; and equivalent changes take place in connection with the lips, palate, and fauces.

The urine is scanty, high-coloured, of high specific gravity, and acid during the early period of typhus, and contains an excess of urea and sometimes of uric acid and of urates, which latter may be deposited. Later on the urine becomes paler and more abundant, and the urea falls considerably below the normal standard. Chlorides are deficient and occasionally disappear during the pyrexial condition. Albumen in small quantities, sometimes accompanied by blood-corpuscles and granular casts, is frequently present in the urine. It is not certain at what date albuminuria generally appears, or when it generally ceases; nor is it a symptom of importance. It is most common, however, in severe cases, and probably usually commences on the third or fourth day.

Pregnant women rarely miscarry; nor does pregnancy or miscarriage add materially to the danger of the patient. The prematurely born fœtus, if old enough, generally survives.

The symptoms referrible to the nervous system always form a characteristic part of typhus fever. Most of these have already been considered. The patient at first has headache, with some dulness and confusion of mind (which impress themselves on his manner and on the expression of his features) and sleeplessness. In a few days he begins to wander at night between waking and sleeping, gradually becoming more stupid and forgetful in the intervals. At the end of the first week, or earlier, the delirium becomes constant, though still worse at night time; and the patient is perhaps drowsy in the day. The delirium, as has been pointed out, may vary in character, but generally soon lapses into typhomania. Gradually the patient becomes more and more unconscious; and, if the case be about to end fatally, he probably falls into profound coma, occasionally preceded by convulsions. The coma sometimes assumes the character of what is termed 'coma-vigil,' in which the patient lies quite unconscious, with his eyes open and fixed. In the early part of the disease there is generally some intolerance of light and ringing in the ears. At the latter part deafness often comes on: and if the patient be comatose the pupils usually contract to mere points. The muscular pains of the first period, the muscular tremors which soon supervene, and the subsultus, floccitatio, and loss of control over the rectum and bladder of the later periods, are all more or less directly dependent on nervous implication.

Typhus fever varies in severity. It is sometimes so mild, of such short duration, and so free from distinctive character, that excepting under the guidance of attendant circumstances correct diagnosis is impossible. In many cases, again, even where the fever is present in a well-marked form, the typhoid stage is never developed; but somewhere between the seventh and tenth day, when usually the patient begins to manifest the gravest symptoms, amendment takes place—the tongue never becoming dry and black, the delirium never occurring at other times than between sleeping and waking. Next, we have the typical case from which our description has been drawn, in which all stages are well developed and the commencement of convalescence is delayed to between

the thirteenth and twenty-first day. Further, we meet with cases in which recovery is delayed by the supervention of complications or sequelæ. And, lastly, cases occur in which the patient dies prostrate and delirious, or comatose, within the first week of the attack or even within the first day or two.

Death is due for the most part to a combination of asthenia and coma. It is most common about the end of the second week. Occasionally, and more in some epidemics than others, the patient dies from the sixth to the eighth day. And many cases are recorded where death has occurred even as early as the first or second day. Death at the end of the first week is often due in some measure to pulmonary congestion; and after the fourteenth day either to this or to some other complication or sequela. The fatality of typhus is considerable. Of patients treated in hospital the mortuary rate is about 15 per cent. But these comprise an exceptionally large proportion of the gravest cases; and there is reason to believe that the death-rate among all persons attacked with typhus is no more than 10 per cent. Among the causes which determine its fatality by far the most important is age. Under twenty the mortality is very low. Dr. Murchison's statistics, taken from the records of the London Fever Hospital, show a mortality in cases under five of 6·69 per cent.; between five and ten, of 3·59 per cent.; between ten and fifteen, of 2·28 per cent.; and between fifteen and twenty, of 4·46 per cent. Between twenty and twenty-five the mortality rises to 10·33; from which date upwards it increases pretty uniformly, lustrum by lustrum, until between fifty and fifty-five it amounts to 49·62 per cent., and between seventy-five and eighty to 84·37.

The sequelæ of typhus are not very numerous or characteristic. Among the more important may be enumerated bronchitis and pneumonia, which may occur during the progress of the fever or during convalescence; gangrene, in the form of bed-sores, or affecting the toes, fingers, nose, penis, or pudenda, or in children mainly in the form of noma; erysipelas; abscesses in the parotid or submaxillary regions, or in the axillæ or groins; suppurative inflammation (said to be pyæmic) of joints; anasarca of legs; and mental imbecility or mania. These sequelæ are all serious; and two of them (noma and suppuration of the joints) are almost invariably fatal.

*Morbid anatomy.*—The post-mortem examination of typhus patients reveals little that is special. There is a tendency in the body to rapid decomposition; the internal organs are for the most part softened and congested; and the blood is dark, stains the vessels which contain it, and coagulates imperfectly. The lungs are usually deeply congested and very lacerable in their dependent parts, and sometimes solid from inflammatory changes. The spleen generally is softened, and not unfrequently is somewhat enlarged. The large intestines occasionally show traces of dysenteric inflammation.

*Treatment.*—It is important that typhus patients should be treated in large, airy, well-ventilated chambers, and therefore that they should be

removed from the overcrowded tenements which as a rule they occupy. The attendants upon them should be seasoned and young. In the later periods of the disease, the bladder should, if necessary, be periodically emptied by means of the catheter, and the patient be kept scrupulously clean, so as to prevent the formation of bed-sores.

The general medicinal treatment of typhus is of little importance. There is no specific remedy, and no means which enable us to cut it short. It is desirable, however, to relieve the thirst from which the patient suffers, and to promote the evacuation by the kidneys of the effete matters which speedily overload the blood. For this reason, so-called 'febrifuge' medicines, which are at the same time mildly diuretic, are doubtless useful. Among them we may enumerate soda-water, and chlorate, nitrate, citrate, or other salts of potash well diluted, acetate of ammonia, and the like. It is desirable also to keep the bowels fairly open either by occasional laxatives or by enemata. On the other hand, if there be diarrhœa, it should be checked by opium or other ordinary forms of astringents. When pulmonary congestion complicates the progress of the fever, a little ipecacuanha or antimonial wine with a few drops of laudanum may be added to the mixture, or, better still, ammonia. If there be much insomnia or acute or busy delirium, opiates in larger doses may be administered by the mouth or subcutaneously, or recourse may be had to chloral or bromide of potassium. Rest, too, may be promoted by cutting the hair short or shaving it, and applying cold lotions or ice to the head. Opiates should not be given when there is any tendency to coma or to suppression of urine. In the typhoid stage ammonia is probably the most valuable medicine.

Whether to exhibit stimulants always becomes an important question. There is no doubt that in a large proportion of cases patients do not require them; but there is also no doubt that many need them, and that few, if any, are injured by them in moderation. In persons of enfeebled constitution, in habitual drinkers, and in such as are of advanced age, it is for the most part desirable to commence their administration early; and in all cases where the heart shows signs of unusual feebleness, where there is extreme prostration, or where typhoid symptoms come on early or are severe, stimulants should at once be had recourse to. The amount to be given under such circumstances must depend on the condition of the patient, and on the effect which they produce. It matters little what form of stimulant is selected.

From the beginning the patient loathes food; but the maintenance of his strength is imperative. Hence, those foods which he can be made to take should be given to him systematically, in small quantities and at frequent intervals. Nothing is better than good milk, of which, by judicious management, from two to three or four pints may often be given daily. But all patients will not take milk. Alternative articles of diet are rice-water, barley-water, gruel, and eggs beaten up with milk, wine, or tea. Beef-tea, broth, arrowroot, and jelly are useful adjuncts. Ice may often be added beneficially to the patient's drinks.

During convalescence quinine or other tonics are important : and the food should be gradually modified to that of health, and should be abundant, frequently administered, and wholesome.

## XII. PLAGUE (*Pestilentia*)

*Definition.*—A contagious fever, closely resembling typhus in its symptoms, but distinguishable from it by the absence of any true rash, and by the development of buboes and carbuncles.

*Causation and history.*—The early history of the disease to which the term ‘ plague ’ is now applied is uncertain. It is known, however, to have prevailed from an early period of the Christian era in the countries which it now mainly affects (namely, Turkey, Asia Minor, Egypt, and Morocco), and to have spread thence at various times over the continent of Europe. In the seventeenth century numerous epidemic outbreaks occurred in Holland and in this country, the last being the Great Plague of 1665. Since then it has occasionally been imported into the countries bounding the Mediterranean basin, and into Russia. In Asia Minor and Egypt it may almost be regarded as endemic ; but occasionally, at irregular intervals, breaks out into terrible epidemics. Whatever the specific cause of plague may be, it is certain that its epidemic occurrence is materially influenced, if not determined, by conditions almost identical with those which determine outbreaks of typhus—namely, privation, filth, and overcrowding. Like typhus, it affects mainly the poor, and is apt to break out in armies engaged in warfare and among the inhabitants of beleaguered cities.

Plague is eminently contagious, and is communicable by the breath, by fomites, and by inoculation. The cause of its spread, therefore, is doubtless a specific contagium. Although an attack of the disease is to some degree protective, subsequent attacks have been abundantly met with.

*Symptoms and progress.*—The duration of the incubative period is uncertain. The symptoms generally commence with chills or rigors, rise of temperature, pains in the forehead, back, and limbs, giddiness, anxiety, and sickness ; on which speedily supervene great loss of muscular power, extreme feebleness of the heart’s action (indicated by rapidity, irregularity, and smallness of pulse, and prostration), and marked dulness or stupidity of expression, with corresponding hebetude of mind, passing quickly into delirium and coma, and sometimes convulsions. The tongue, thickly coated from the beginning, soon becomes dry and black. The bowels are generally somewhat loose, the urine scanty and occasionally suppressed. And hemorrhages from the various mucous surfaces are not unfrequent.

Within two or three days after the first appearance of symptoms petechiæ not unfrequently appear over the surface of the body ; and besides these, the more characteristic glandular swellings or buboes, which are

chiefly to be detected in the neck, axillæ, and groins. Subsequently carbuncles become developed at various parts of the surface, generally, however, in the extremities. The appearance of petechiæ is by no means invariable, and is regarded as being of bad augury. The buboes enlarge, sometimes to a considerable size, reach their height (if the patient survive so long) at about the end of the eighth or ninth day, and then either subside or (more rarely) suppurate. Carbuncles are comparatively unfrequent, and for the most part show themselves towards the decline of the disease; they vary in size and intensity of inflammation, and in numbers from one to about a dozen.

Death from plague sometimes takes place within twenty-four hours after seizure. Severe cases not unfrequently prove fatal on the second or third day of the disease. Many patients die on the fifth or sixth day. Occasionally death is delayed until the second or third week, but is then probably due mainly to the effects of complications.

It is generally acknowledged that it is impossible to distinguish plague positively from typhus, either by its early symptoms, or by the first few cases that come under treatment—the mode of invasion and the general symptoms and progress of the two diseases presenting many points in common. Petechiæ are frequent in both diseases, and buboes are of occasional occurrence in typhus. But plague does not present the true typhus rash; and the buboes, which are quite exceptional in typhus, are almost constant in plague; and, further, the mortality of plague is much greater than that of typhus, and its fatal issue occurs much earlier.

*Morbid anatomy.*—Patients dead of plague show, as in typhus, a tendency to rapid decomposition, fluidity or imperfect coagulation of blood, congestion, softening and enlargement of organs, and petechial extravasations beneath the serous and mucous surfaces. But besides these phenomena, there is a general enlargement of the lymphatic glands, which vary individually from the size of a goose's egg downwards. This enlargement is not limited to the superficial glands, but involves those of the interior of the thorax and abdomen, and is often attended with congestion and softening, and in some cases with suppuration.

*Treatment.*—The rules and details of treatment which have already been given in regard to typhus are applicable to plague. No specific remedies are known. Buboes and carbuncles call only for the usual treatment of such affections.

---

### XIII. RELAPSING FEVER (*Famine-Fever*)

*Definition.*—A contagious disorder, characterised by a sudden attack of high fever, lasting for about a week; and then apparent convalescence, followed after about fourteen days from the primary accession by a second attack of fever. A further relapse now and then occurs about the twenty-first day.

*Causation and history.*—The geographical limits of relapsing fever have not been fully ascertained. Our knowledge of it has been chiefly derived from epidemics originating in Ireland, whence it has spread to England and Scotland. It appears also to have broken out independently in Scotland. Epidemics of it have, within the last few years, been observed in Russia and Silesia; and also in America, India, and parts of Africa. There seems to be a close relation between starvation and relapsing fever, which has hence been denominated famine-fever. All the more recent and most fully investigated epidemics appear to have arisen during the prevalence of extreme destitution, and among the classes that have mainly suffered from destitution. Further, although the disease is highly contagious and liable to affect all who come within its influence, it is mainly carried by tramps and vagrants; and, when it spreads among populations not suffering from famine, still chiefly affects those sections of them that are least well-fed. Overcrowding and filth are almost necessary accompaniments of famine; but these are not thought to have any special influence in the production of relapsing fever. At all events, when these conditions exist (as they often do) independently of famine, they are never known to promote the outbreak of the special famine-fever. Season and other climatic conditions appear to exert no influence over its development or spread; and its attacks are probably in no degree determined by age or sex; although it is true that statistics show a larger proportion of sufferers among males than females. The contagion of relapsing fever is carried by the atmosphere, and also by fomites. But there is good reason to believe that its influence extends but a short distance around the patient, that it is readily lost by dilution, and that in order to ensure its action a large dose of poison or a long exposure to it is essential. The specific cause of the disease, as we have already shown (page 138), is a cork-screw-like, actively moving bacterium, which abounds in the blood during the febrile paroxysms. A marked peculiarity of relapsing fever, as compared with other diseases of its class, is the fact that one attack does not confer safety from subsequent attacks; at all events, many persons have been known during one and the same epidemic to suffer from it two or three times at short intervals. It may be remarked, however, that the fact of a patient recovering spontaneously from an infective disease is a proof that he enjoys at least a temporary freedom from liability to be affected by it. And hence it may be assumed that immunity is actually conferred by an attack of relapsing fever, but that the period of immunity is mostly of very short duration.

*Symptoms and progress.*—The latent period of relapsing fever varies. Its extreme limits are probably two and sixteen days. Cases, however, are recorded in which the attack seemed to follow almost immediately on infection. Dr. Murchison concludes that the period of incubation is, on the whole, shorter than that of typhus.

The onset of the disease is for the most part sudden. The patient is seized with a feeling of chilliness or with rigors, attended with severe pains in the forehead, trunk, and limbs. This condition is soon followed

by intense heat and dryness of surface, increased frontal headache, lumbar and other pains, giddiness, frequency of pulse, thirst, and loss of appetite. The latter symptoms continue with some slight variation (the dryness of skin, however, frequently alternating with perspirations) until the third, or more commonly the fifth or seventh day of the disease; when, often preceded by a slight rigor, a copious perspiration almost suddenly breaks out, which lasts for a few hours, and is then followed by a remarkable reduction in the rate of the pulse and of temperature, and, with the exception of some remaining lassitude, almost complete restoration to health.

The following is a more detailed account of the several symptoms which attend the febrile attack. The temperature almost from the commencement is very high, often ranging from  $104^{\circ}$  to  $108.5^{\circ}$  F.; the pulse is rapid, generally over 110, and often reaching 130 or 140 in the minute; the tongue is thickly coated with a white fur (the tip and edges being red), and occasionally towards the termination the centre of the organ gets dry and brown; the teeth are free from sordes; the patient suffers from extreme thirst, generally from anorexia and often from vomiting; in rare cases there is slight hæmatemesis; the bowels are mostly constipated; there is often considerable tenderness in the region of the liver and spleen, both of which organs become increased in size, and in many cases jaundice appears about the second or third day; the urine varies in quantity, but presents an excess of urea, and occasionally contains albumen and even blood—toward the latter period of the attack suppression may take place; the pains in the head, trunk, and limbs continue, all being severe, and the latter mainly affecting the joints and presenting, therefore, a rheumatic character; the patient for the most part retains perfect consciousness, but generally suffers greatly from want of sleep and from frightful dreams when he does sleep; delirium, which may be maniacal, sometimes occurs about the period of the crisis; stupor, coma, and even convulsions supervene, though rarely, about the same period, and are then probably due to uræmic poisoning. The patient seldom presents the congested conjunctivæ and dull puzzled aspect of typhus fever. The critical perspiration is occasionally attended with, or replaced by, an attack of diarrhœa, or of hemorrhage from the nose, bowels, or elsewhere. No rash is ever seen, except perhaps a few petechiæ towards the end.

During the intermission the temperature often sinks below the normal, to  $96^{\circ}$ ,  $94^{\circ}$ ,  $92^{\circ}$ , or even  $90.6^{\circ}$ , and it continues low for the first two or three days; the pulse also drops to 60, 50, or 40 in the minute, though liable to sudden increase on exertion; the tongue becomes clean, and the appetite often voracious. Occasionally, at the commencement of this period, the patient falls into sudden collapse, or passes into a typhoid state; but far more frequently, with the exceptions above adverted to, he appears to be restored to perfect health.

Sometimes the first paroxysm of fever is the only one. But more commonly, at the end of fourteen days (more or less) from the first accession of symptoms, the patient suddenly experiences a recurrence of his

febrile attack. The symptoms which now ensue are as nearly as possible identical with those from which he formerly suffered. The temperature, however, is often higher, and the duration of the attack for the most part shorter. It generally lasts about three days; at the end of which time convalescence is ushered in with the phenomena which previously ushered in the remission.

Occasionally a third paroxysm takes place on or about the twenty-first day; and a fourth and even a fifth recurrence have been observed, though very rarely.

The danger to life from relapsing fever is comparatively very slight. Dr. Murchison's statistics show a mortality of only 4·75 per cent. The statistics of mortality, however, of an epidemic prevailing in Philadelphia in the winter of 1869-70 seem to show that it is much more apt to terminate fatally in the negro than in the white race. The causes of death are mainly asthenia and collapse (the latter of which may occur suddenly about the period of crisis), coma and other cerebral complications, and its sequelæ.

Convalescence is generally protracted (the patient very slowly regaining strength), but seldom complicated with serious sequelæ. Amongst the most common of these are pulmonary affections (more especially pneumonia), diarrhœa, and dysentery. The most characteristic of them all is ophthalmia. It is a remarkable fact that pregnant women affected with relapsing fever almost invariably abort, and this no matter what period of gestation they may have reached. The fœtus, moreover, dies; the mother, as a rule, recovers.

*Morbid anatomy.*—Excepting for the presence of such lesions as are due to accidental complications and sequelæ, nothing very characteristic is noticeable after death. The liver is usually enlarged and congested, but otherwise (even if jaundice be present) apparently healthy; and the spleen is invariably enlarged to several times its normal bulk, and generally softened or diffuent.

*Treatment.*—In the treatment of this disease it is of course necessary, in order to prevent its spread, to isolate the sick, and to take the ordinary precautions in respect of ventilation and the like. In every case the disease will probably run its course, whatever treatment be adopted. It is important, nevertheless, to alleviate symptoms and to avert complications. To diminish heat, cold sponging or the graduated bath may be serviceable; to check vomiting, ice; to relieve headache and other pains and to promote sleep, perfect quiet, opium or morphia in medium doses, chloral, and counter-irritant or sedative applications; to obviate constipation and portal congestion, mild laxatives such as castor-oil, or enemata; and to encourage diuresis, non-stimulating diuretics, such as bland drinks, and medicines containing chlorate, nitrate, or acetate of potash, or acetate of ammonia. If coma, attended with suppression of urine, occurs, it may be necessary to give purgatives, and to apply cupping-glasses over the lumbar region. Emetics are recommended by many to be given early in the disease; and bleeding has also been strongly advocated. During the

febrile attack, the nourishment should be such as is usually proper for patients suffering from febrile disorders. Alcoholic stimulants are rarely necessary, excepting when there is tendency to collapse.

---

#### XIV. DENGUE (*Dandy Fever*)

*Definition.*—A specific affection, characterised by high fever, inflammation of the joints, a peculiar rash, and a tendency to be continued for a few weeks by intermittent attacks of short duration.

*Causation and history.*—Nothing seems to have been known of this disease until the year 1824, when it broke out suddenly in Rangoon among a body of troops. Thence it spread; and since that time it has occurred in occasional epidemics in different parts of India, and also in the tropical parts of North America and in the West India Islands, into which it was introduced from the East Indies. It does not appear to have extended to temperate regions. Dengue is contagious in a very high degree, and doubtless, like other such diseases, depends upon a specific virus communicated from the sick to the healthy. Its contagiousness, indeed, is almost as virulent as that of influenza, and it spares neither male nor female, young or old.

*Symptoms and progress.*—Little or nothing is known with respect to the period of incubation of dengue, or the amount of protection one attack affords. The invasion is sometimes preceded by slight premonitory symptoms, but much more frequently is sudden. Among the early phenomena of the disease are: high fever, with sense of chilliness or actual rigors, alternating with flushes of heat; dryness of skin; severe frontal headache with vertigo; aching in the eyeballs; pain along the spine and in the limbs, but more particularly in the joints; great rapidity and hardness of pulse; acceleration of respiration; furred tongue, and heat and pain at the epigastrium, with loss of appetite and very frequently sickness; great muscular prostration, restlessness, and inability to sleep. With the advance of the disease, the prostration and the febrile symptoms undergo aggravation; the face and the conjunctivæ become congested; the pulse rises to 120, 130, or even 140; the tongue gets coated, except at the tip, with a thick, white, moist fur; and the pains (especially those in the joints) are augmented—the arthritic pains, indeed, tending to shift about as in ordinary rheumatism, and the affected joints (especially the smaller ones) to swell. In the course of a day or two, however, perspirations break out, and the severity of the symptoms seems to abate somewhat; but on the third or fourth day of the disease, or a little later, some increase of pain takes place, and is attended with an evanescent eruption, which, commencing on the hands and feet, quickly spreads over the whole cutaneous surface. This eruption has been likened to that of scarlet fever, measles, urticaria, or erythema. From the descriptions it would seem to be a kind of erythema papulatum, such as is not unfre-

quently met with in cases of acute rheumatism. It is said to disappear usually on the second day, to be attended with more or less itching, and to be followed by desquamation. It is not always present. With the subsidence of the rash, or about the fifth, sixth, or seventh day of the disease, the febrile and other symptoms abate, the patient becomes convalescent, and is then soon restored to comparative health. In a short time, however, a relapse almost as severe in its symptoms as the primary attack, but lasting only for two or three days, occurs; and to this, after intervals of apparent convalescence, a second and perhaps a third relapse succeed. Usually much debility, and not unfrequently pain, stiffness or swelling of the joints, persist after the final cessation of fever; and health is generally not completely restored under a period of three months. It is important to observe that, notwithstanding the high fever, the extreme pain, and the general severity of the symptoms under which the patient labours, he rarely suffers from delirium, or fails to make a good ultimate recovery. Occasionally death occurs early in the disease (during the period of defervescence) from syncope.

Other phenomena which patients suffering from dengue occasionally present are: bleeding at the nose; swelling of the parotids with salivation; swelling of the lymphatic glands, or of the testicles; jaundice, and ophthalmia. It may be added that the appetite in some cases continues unimpaired, and that pregnant women rarely abort.

It is obvious that the phenomena of dengue have a considerable resemblance, in some aspects, to those of rheumatism, ague, scarlet fever, and measles, with each of which it has been confounded. But it much more closely resembles relapsing fever. It resembles this, in its virulence of contagion, in its sudden access, in its high temperature with headache and arthritic pains, in the rareness of the occurrence of delirium, in its tendency to be continued by several successive relapses, in its little mortality, in some of the details of symptoms and sequelæ (such as the condition of tongue and appetite, the occasional occurrence of jaundice, ophthalmia, and inflammation of the salivary and other glands), and even in the occasional supervention of death from syncope during the period of defervescence. The eruption of dengue (if it be specific) may seem to indicate a difference between them, as also may the intensity of the arthritic inflammation which attends it.

Of the *morbid anatomy* of dengue nothing of any importance is known.

*Treatment.*—The treatment must be that applicable to other fevers over whose course we have no control. Emetics and purgatives have been strongly advocated. But, on the whole, it is probably best to administer saline or other cooling medicines. The headache and arthritic pains may be relieved by local applications, or by the use of opiates; and complications may call for special treatment. During convalescence, quinine or other tonics are indicated.

---

## XV. YELLOW FEVER

*Definition.*—A spreading continued fever, of short duration, characterised especially by epigastric tenderness, vomiting, hæmatemesis, and jaundice.

*Causation and history.*—This disease prevails in certain tropical regions, mainly in the West India Islands, which seem to be its home, and in the neighbouring portions of the continents of North and South America. But it occasionally invades countries correspondingly situated in the Old World, and has even been introduced into the seaport towns of England, France, and other parts of Europe. It seems never to spread, however, in these latter places, excepting at times of excessive heat. A high temperature appears to be an essential condition of its prevalence. It is said, indeed, that it never spreads when the thermometer stands at less than 72° Fahr., and that, even when it is epidemic in a place, it rarely if ever attacks those who live more than 2,500 feet above the level of the sea. Outbreaks of yellow fever are probably promoted by local conditions of general insalubrity; and the intensity of the disease is doubtless augmented by them. Its contagiousness is denied by many, especially American, writers. It is admitted, however, that it attaches itself to fomites, and that it may be carried by infected ships into healthy seaport towns, and there produce local outbreaks. The evidence, therefore, in favour of its contagiousness is very much of the same nature as that in favour of the contagiousness of epidemic cholera and enteric fever. We regard it as contagious, and as the product of a specific virus given off from the bodies of the sick. There is no good reason to believe that it ever arises spontaneously. It spares neither age nor sex; but one attack confers on the sufferer immunity from other attacks. Cocci have been detected in the vessels of the liver and kidneys.

*Symptoms and progress.*—The period of latency of yellow fever is said to vary between two and fifteen days. Most commonly it ranges from six to ten. At the end of this time the patient is generally attacked suddenly with acute febrile symptoms marked by shivering, increased temperature (101° to 105°), dryness of skin, congestion of face, redness, suffusion and aching of eyes, acceleration of pulse, thirst, anorexia, pains in limbs, and intense frontal headache; to which are soon added acute lumbar and spinal pains, slight epigastric tenderness, and vomiting of the mucous and other contents of the stomach. The tongue is generally coated with a thick creamy fur, except at the tip and edges, which are preternaturally red. After these symptoms have lasted, with some variation, for a day or two, the febrile condition and the intense frontal and rhachidian pains are apt to subside somewhat. But, for the most part, the epigastric tenderness becomes more pronounced and the vomiting more constant; and slight yellowness of the conjunctivæ may perhaps be recognised. On the third or fourth day, or later, the vomited matters,

hitherto colourless or yellow, begin to contain blood (sometimes bright, more commonly in the form of suspended particles of black pigment), and they soon assume from this cause a coffee-ground character, constituting the so-called 'black vomit.' At the same time the motions are often dark or black from the presence of blood. If the patient do not at once sink, symptoms of a typhoid character are apt to supervene; the vomiting may or may not continue; the skin probably becomes more decidedly jaundiced and at the same time dusky, the teeth covered with sordes, the tongue dry and black, the pulse quick and feeble; an eruption of red spots or of petechiæ often makes its appearance on the trunk; and drowsiness, convulsions, delirium, maniacal excitement, or coma supervenes. From the second or third day the urine contains albumen, and occasionally a little blood. Later on it is scanty, and sometimes suppressed.

Convalescence may (according to the severity of the attack) commence from any period of the disease, is marked by the gradual subsidence of the graver symptoms, and is generally completed at the end of two or three weeks. The jaundice, however, is slow to disappear. The fifth day is often regarded as critical.

The mortality from yellow fever is very high, and death occurs at various periods in its course. In some cases the attack is so sudden and so severe that the patient dies in a state of collapse at the end of a few hours. More commonly he sinks at the end of two, three, or four days, during the period of black vomit—his death then being often due to sudden collapse probably determined to some extent by gastro-intestinal hemorrhage. Death is not unfrequently thus produced at this time in patients who have seemed to be going on quite favourably, and even in those who have hitherto suffered so little from the disease that they have not been confined to bed, and have been able to follow their employments. At a later date death is due, sometimes to cerebral complications, probably referrible to uræmic poisoning, sometimes to gradually increasing exhaustion.

The symptoms which collectively are most characteristic of yellow fever are, sudden onset with high fever, frontal and lumbar pain, epigastric tenderness, hemorrhagic vomiting, and jaundice. But any of them, and more especially the last two, may be absent. Indeed, the symptoms of the disease are liable to great variation, dependent in large measure on the greater or less severity of the attack, and on the relative degrees in which the several parts of the organism are affected. Mild cases of the disease often present no characteristic features whatever, and may be readily confounded with similarly mild attacks of other continued fevers.

In its sudden onset with frontal headache, lumbar pain, and vomiting, yellow fever closely resembles variola, from which, however, it soon becomes differentiated. Relapsing fever, again, in its sudden development with fever, headache, pain in the back, and vomiting, followed in a day or two by jaundice, presents a marked resemblance to yellow fever; but it differs from it widely in its little fatality, in the absence of black vomit, in

its sudden cessation at the end of a few days, and in the subsequent relapse. Malarial remittent fevers may also be confounded with yellow fever, but are distinguishable by many features : they are endemic and not contagious ; one attack favours subsequent attacks ; the febrile paroxysms intermit ; there is enlargement of the spleen ; and gastro-intestinal hemorrhages, if they occur, are copious and sudden. Yellow atrophy of the liver may be distinguished by its gradual commencement, without marked fever, pain, or other characteristic symptoms of yellow fever ; at a later period, when the skin becomes yellow, the epigastrium tender, and delirium supervenes, the diagnosis may be difficult. Lastly, it may be remarked that jaundice is not uncommonly developed in the course of various fevers and inflammations, and cannot therefore be regarded as a distinctive mark of yellow fever.

*Morbid anatomy.*—The principal morbid conditions observed after death from yellow fever are, as might be predicted from the symptoms, to be discovered in the liver and mucous membrane of the alimentary canal. The liver is generally pale, soft, yellowish or clay-coloured (as it is in many other acute febrile states attended with jaundice), more or less fatty and somewhat enlarged. The mucous membrane of the stomach is for the most part soft and injected, and the cavity of the organ usually contains disintegrated and blackened blood. Similar congestion and similar contents may also be met with in the intestines. Peyer's patches are unaffected. The spleen is soft, but not enlarged. Hemorrhages are not uncommonly met with in the lungs and various other parts. Nothing else noteworthy has been detected.

*Treatment.*—Many drugs have been recommended and used in the treatment of this disease. Large doses of calomel and large doses of quinine have both been tried. But it seems probable that they have done no good, if not harm. The patient should be confined strictly to bed, and not allowed to make any exertion. He should be kept cool, in an apartment well ventilated and devoid of hangings. The secretions of the skin and kidneys should be encouraged by diluent drinks, and the bowels kept freely open—preferably by enemata. Vomiting should be counteracted by ice, and medicinally by lime-water, hydrocyanic acid, spirits of chloroform, bismuth, or other stomach-soothing drugs. Wakefulness and delirium may be treated with opiates ; headache, precordial uneasiness, and lumbar pains relieved by the local application of counter-irritants, cold, or anodynes. Constant vomiting generally precludes the successful administration of food. Under any circumstances, however, this should be bland and unirritating, and given frequently and in small quantities. Nothing can be better than milk, barley-water, rice-water, or gruel. No doubt the great tendency to fall into collapse is suggestive of speedy recourse to alcoholic stimulants. Of these brandy and the effervescent wines have been most recommended. But they should be given diluted and with caution ; for, however beneficial they may prove if absorbed, their local influence on an irritable and bleeding stomach can scarcely be other than injurious.

## XVI. CEREBRO-SPINAL FEVER (*Epidemic Cerebro-Spinal Meningitis*)

*Definition.*—A specific contagious fever, characterised by inflammation of the membranes of the brain and cord, and the symptoms which these lesions induce, and frequently attended with petechiæ, collapse, and early death.

*Causation and history.*—This disease has only been distinctly recognised from the time of its epidemic prevalence in various parts of France between the years 1837 and 1848. Since its first appearance in that country, it has broken out at various times in Italy, Algeria, Gibraltar, Portugal, Holland, Denmark, Sweden, Norway, North Germany, and Ireland. In Ireland the disease prevailed between the years 1846 and 1850, and again with considerable severity between 1865 and 1867. In Dantzic a notable epidemic occurred in the years 1864 and 1865. In the United States cerebro-spinal fever became prevalent about the same time as in France, and since then there have been frequent outbreaks in different parts of that country. It is by no means clear that there has ever been any prevalence of the disease in Great Britain. Age and sex, social condition, and ordinary sanitary circumstances appear to exert little influence over the origin and spread of cerebro-spinal fever. Nevertheless, males seem on the whole to have suffered in larger proportion than females, and soldiers in garrison, in many epidemics, more severely than other sections of the population. It appears, also, to be indisputable that the disease occurs mainly during the winter months; and Mr. Netten Radcliffe remarks that 'it is noteworthy that the northern and southern limits of distribution in both hemispheres but slightly overlap the isothermal lines 5° and 20°.' Cerebro-spinal fever is certainly epidemic. Is it also infectious? Of this we think there can be little doubt. It is important, however, to note that the mode of its epidemic prevalence is not unlike that of cholera or typhoid fever, in the facts that it is marked by numerous scattered and for the most part small outbreaks, rather than by a general widespread diffusion; and that the disease, like these others, although giving clear indication of its spread from the sick to the healthy, presents little or nothing of the virulence of direct contagion which characterises most of the exanthemata. Micrococci have been found in the membranes of the brain and cord, and in the inflammatory exudation.

*Symptoms and progress.*—Cerebro-spinal fever is attended in some cases by premonitory symptoms, lasting from a few hours to several days, and comprising mainly feverishness, malaise, headache, and pains in the back, abdomen, and limbs; but in many cases it comes on quite without warning. In either case the first symptoms of the actual outbreak are: severe rigors; intense headache with vertigo; persistent vomiting with more or less severe pain in the stomach; and pains along the spine and in the muscles of the extremities, often attended with spasmodic con-

traction. The patient soon becomes restless or irritable, voluble or taciturn, more or less obviously delirious or the subject of delusions, and not unfrequently drowsy. His head is thrown back and retained in that position; not so much from spasm in the muscles of the neck as from a voluntary effort to relieve pain in that situation; and his limbs become flexed. He probably cries out at times, or screams with the intensity of the pain in his head and back. But gradually his mind gets more distinctly affected; he becomes less alive to pain and other subjective phenomena; he passes into a condition of busy or muttering delirium or into one of acute maniacal excitement, occasionally has convulsions, and then lapses into profound coma. In many cases a purpuric eruption makes its appearance from the second to the fourth day. Death may occur during the first day or two (occasionally after a few hours only) from collapse; or, from this time to the seventh or eighth day, from coma due to the cerebro-spinal lesion; or at a later period, even up to the sixth or seventh week, from one or other of the complications which are apt to ensue.

The above is a sketch of the symptomatic phenomena of the disease in its ordinary form; and, as will be observed, they are mainly those of non-specific inflammation of the membranes of the cord and brain. They vary much, however, in their severity in different cases, and are frequently conjoined with other symptoms which are also for the most part dependent on the cerebro-spinal lesion. We will consider them *seriatim*, as they are referrible to different conditions and different organs. *Fever* is not usually a marked feature of the disease. The temperature appears in many cases never to rise above  $101^{\circ}$ ; but it may reach  $105^{\circ}$ ; and in cases which are rapidly fatal, with symptoms of collapse, it may even sink below the normal. The *skin* varies in its condition, but is seldom pungently hot and dry, or profusely perspiring. Besides the petechial eruption which has been described it occasionally presents patches of erythema or roseola; or groups of herpetic vesicles appear upon the lips. *Respiration* in severe cases is more or less embarrassed. It is then generally slow and suspirious, but with the increase of depression becomes hurried and shallow. The *pulse* is much enfeebled, but its frequency is liable to great variation; sometimes it is preternaturally slow, sometimes exceedingly frequent; and rapid alterations are apt to occur without any obvious cause. The *gastro-intestinal* phenomena are of some importance. Violent sickness is a noteworthy symptom of the disease during its earlier periods. It comes on without any necessary sense of nausea, and independently of the ingestion of food. As the disease advances it usually ceases. The severe abdominal pain which commonly occurs about the same time is also an important symptom; it appears to be strictly neuralgic, and like the vomiting itself referrible to the condition of the central nervous organs. The tongue may be clean or furred, and with the progress of the disease is apt to become dry. The bowels are for the most part constipated. The *urine* in some cases contains albumen and blood. The more important symptoms referrible to the *nervous system* (namely,

neuralgic pains, delirium, and coma) have already been enumerated, and we need not recur to them. We may, however, point out that numerous additional phenomena are apt to present themselves. The patient not only suffers from intense pain in the head, not necessarily limited to any one locality, but also from pain in the course of the spine and especially in its cervical region, and from neuralgic pains in the belly and in the course of the limbs. Cutaneous hyperæsthesia is sometimes present. We have pointed out that general convulsions are occasionally observed ; but more common perhaps than these are local spasms either of the tonic or of the clonic kind in various groups of muscles, or tremors and subsultus. Paralysis, either hemiplegic or limited to a limb or some other portion of the organism, occasionally supervenes ; or there may be anæsthesia. Deafness, loss of sight, squinting, inequality of pupils, and the like, are also occasionally met with ; and sometimes, intolerance of light or sound. With the supervention of coma, and often before that period, there is loss of control over the bladder and rectum. The *attitude* which the patient assumes is characteristic at all events of cerebro-spinal inflammation ; and his *aspect* generally affords clear indications of the condition of his cerebral and spinal functions.

If the case be of long duration, various phenomena, due apparently to irritation of the nerves or of the centres whence they emerge, are apt to ensue : and amongst them, destructive inflammation of the cornea, or other parts of the eye, or of the internal ear ; inflammation, often attended with suppuration, of the large joints ; parotid swellings ; and bed-sores. Inflammatory affections of the thoracic organs are also not unfrequent.

The percentage of deaths in cerebro-spinal fever has varied in different epidemics between 20 and 80.

*Morbid anatomy.*—The morbid changes observable after death are definite and simple. They consist in congestion of the vessels of the pia mater of the brain and cord, and inflammatory exudation into the sub-arachnoid tissue and occasionally into the ventricles. This exudation may be transparent and watery, but is more frequently opaque, greenish, and distinctly purulent. The affection is sometimes general, but more commonly localised to some extent ; and not unfrequently it is confined mainly to the base of the brain (especially its posterior part) and to the surface of the medulla oblongata and upper part of the spinal cord. There is often, also, congestion of the substance of the brain. It is said that in some cases in which death has occurred speedily from collapse no characteristic lesions have been detected.

*Treatment.*—The treatment of cerebro-spinal fever has probably not been more successful in its results than that of any other of the specific fevers. It must, however, be borne in mind that the mortality of this disease is due less to the direct influence of the specific poison of the disease, than to the cerebro-spinal inflammation which is one of the immediate consequences of its operation. If, therefore, meningeal inflammation be amenable to treatment, it is reasonable to believe that that of

cerebro-spinal fever should be to some extent within our control. Powerful depletory measures, however, and above all the abstraction of blood, are on several grounds obviously contraindicated. Counter-irritation, or cold to the head and along the spine, and moderate purgation, may possibly be of some benefit, as also may cooling saline draughts. Opium in large and frequently repeated doses, and quinine in large doses, have found much favour with American physicians. The food which is administered should be in the fluid form, and its regulated exhibition should be enforced. When symptoms of collapse manifest themselves, stimulants may be had recourse to, and the surface should be kept warm.

---

## XVII. DIPHTHERIA (*Membranous Croup*)

*Definition.*—A contagious disease, of which the more characteristic phenomena consist in the formation of whitish membranous pellicles on certain mucous surfaces (more especially those of the fauces, nares, larynx, and trachea), and on excoriated or wounded areas of the skin; the rapid development of anæmia and extreme debility; and the supervention, during apparent convalescence, of temporary paralysis.

*Causation and history.*—This disease, although it has been described by many authors of ancient and modern times, has been known by its present name only since the publication of Bretonneau's treatise in the year 1826. He designated it 'diphthérie' (since modified into diphtheria) from the Greek word *διφθέρα*, a skin. Diphtheria, like most other infectious diseases, is met with in the sporadic form, and from time to time breaks out into virulent and widespread epidemics. Many of these have been recorded. The last of any serious importance prevailed in France during the years 1855, 1856, and 1857, and was imported thence into our own country, where, from 1859 to 1862, it committed great ravages. It was then regarded by a large number of the most experienced physicians as a disease almost, if not quite, new to the country. They were well acquainted with membranous inflammation of the trachea, or croup—a disease, too, which had been known to occur in an epidemic form; but they failed to see, as many indeed still fail to see, that between the characteristic forms of croup, from which the classical description of the disease was taken, and diphtheria, there is no essential difference. The Scottish and English physicians of the latter part of the last century, and the early part of this, had their attention particularly directed to the rapidly fatal laryngeal form of the disease, and described it as a local malady. Bretonneau, on the other hand, recognised that the laryngeal affection was only the occasional complication of a general disease, which was infectious, and presented other remarkable features besides the mere formation of a membranous lining to the air-passages.

Thus, the same disease, described from different points of view and from different degrees of acquaintance with its pathology, and receiving

different names, came to be regarded as two distinct diseases. And hence as much confusion has arisen, and as much difficulty in recognising the exact truth, as in the converse case of disentangling enteric fever and typhus from the discordant descriptions of the presumed single disease, continued fever.

Diphtheria is a disease of all countries and all seasons, and affects both children and adults. It is, nevertheless, far more common among young children, especially between the ages of three and six, than in persons of more mature age, and is both actually and relatively much more fatal to them. There is reason to believe that the sanitary state of houses or localities, and the condition of health of those who are exposed to its poison, have much influence over its development. It is not very clear, however, what forms of uncleanness or what constitutional conditions are most influential in this respect; for we know that those who appear to be in the best of health often take it, while the weakly often escape; and that it attacks the wealthy and the clean as well as the poor, the filthy, and the overcrowded. Diphtheria is undoubtedly contagious; the epidemic of 1859-62 was distinctly imported into this country from France; the introduction of a case into a house, hospital, or other institution containing many inmates, is almost certain to be followed by an outbreak of the disease amongst them—and indeed it not uncommonly happens that every child of a large household is thus swept away; the nurse contracts it from her charge, the doctor from his patient, the mother from her suckling. The contagion is carried by the atmosphere. But it may also lie dormant in fomites, and thus present prolonged vitality; for it is certain that many cases have been met with in which children, brought into rooms which had been well purified subsequently to the occurrence of diphtheria in them several weeks or months previously, have taken the disease. There is no doubt that it can be imparted by inoculation. Professor Valleix suffered from a fatal attack due to the reception into his mouth of a small quantity of saliva coughed out by a diphtheritic child; and many a person has died from diphtheria brought on by sucking, in order to clear it, the cannula fixed in the throat of a tracheotomised diphtheritic patient. Experiments upon the lower animals have been largely performed, but with results which are not entirely conclusive. The most important are those of Letzerich, Oertel, and Trendelenburg, in which they claim to have given diphtheria to rabbits by the introduction of diphtheritic matter into the trachea. It is generally believed that the virus of the disease may be conveyed by means of sewer gases.

It may be presumed that the patient is most apt to impart the disease while the membranous exudations are present; but it is by no means certain at what period he ceases to be infectious. Convalescent children (children, that is, who appear to be perfectly well and have been apparently well for two or three weeks) seem occasionally to give the disease to others.

*Symptoms and progress.*—The period of incubation is not accurately

known. Some patients appear to have had the first symptoms of diphtheria a few hours only after exposure to its virus. In others the disease has not manifested itself for eight days. The incubative period probably varies between these extremes. Whether it is ever longer must be regarded as doubtful. The symptoms of invasion vary in some degree in their intensity with the virulence of the attack they usher in. For the most part they consist in elevation of temperature and other evidences of febrile disturbance, together with slight uneasiness, or soreness of the throat. But these are often so slight that the patient makes little or no complaint, and pursues his ordinary avocations, until perhaps (especially if he be a child) attention is attracted to him by the presence of pallor, languor, and dulness or tendency to mope. Sometimes the febrile symptoms are much more marked, and there may be distinct chills or rigors; but there is rarely even then any great complaint as to the condition of the throat. If, on the first evidence of illness, the interior of the throat be examined, there will probably be observed some degree of redness and tumefaction of the tonsils, pillars of the fauces, soft palate or pharynx, or of all these parts. And very soon afterwards, whitish, greyish or buff-coloured, opaque, well-defined patches will be visible on some parts of the congested surface—often on one or both tonsils. These vary in thickness, are more or less coherent, admitting of removal in shreds or as a whole, and are moderately adherent to the subjacent surface, which is left excoriated but not excavated by their removal. They tend to spread rapidly, and hence if multiple to coalesce, and at the same time to become thicker and more adherent; and may thus, in the course of a few days, form a nearly continuous covering to the whole surface above indicated, including that of the uvula. And, indeed, the throat may be found already in this condition, at the time when attention is first seriously attracted by the general aspect of illness which the patient presents. By this time, the tonsils are often considerably enlarged, and the uvula swollen and œdematous; there is almost invariably manifest swelling and tenderness of the lymphatic glands about the angles of the jaw; there is generally, also, more or less mucous exudation and accumulation about the fauces; but rarely, either the total loss of appetite, or the great agony in mastication and swallowing, which attends ordinary tonsillitis.

The course which the disease may take from this point is very various. In some cases, the febrile symptoms soon subside, the morbid process ceases to spread, and the patient rapidly convalesces. In some cases the membranous formation extends along the œsophagus, reaching, it may be, to the stomach. In some, it spreads to the larynx and trachea, and occasionally thence to the bronchial tubes. In some it invades the posterior nares, extending possibly throughout the whole of the nasal cavity and even along the lacrymal ducts to the conjunctivæ. In some, the inflammation spreads in depth, and the glands and other soft tissues in the submaxillary and adjacent regions get swollen and infiltrated with inflammatory matter. And in some, diphtheritic pellicles make their

appearance on other mucous surfaces, or on excoriated or ulcerated parts of the skin. We will discuss these various cases categorically.

1. The first of the above varieties of diphtheria is often a very mild disorder. The patient (with little or no fever at any time, and scarcely any complaint of soreness of throat, with no material thirst or loss of appetite, and with perhaps a small white patch on one or other or both tonsils, which may even have disappeared before the throat comes to be examined, or which may be detached at the end of three or four days or a little later) becomes convalescent in the course of a week or ten days, and then, except probably for some unusually persistent anæmia and debility, and perhaps for some enduring enlargement of the cervical glands, is soon restored to health. When, however, the membranous exudation covers an extensive surface (especially if, at the same time, the tonsils and uvula are much swollen), the symptoms are far more serious, and the duration of the malady is prolonged; but even then, if no complications arise, the patient is generally convalescent at the end of ten days or a fortnight. There is commonly under these circumstances great and increasing debility and anæmia; and not unfrequently the patient, who has been perfectly sensible all along, dies from asthenia or in a fainting fit following some slight exertion. Occasionally, and more commonly in adults than in children, the breath acquires a fetid and distinctly gangrenous odour, the false membrane at the same time assuming a dirty grey or blackish hue, and a more or less pultaceous consistence. These phenomena are seldom due to actual gangrene, but are generally the result of mere decomposition of the diphtherial exudation.

This is perhaps the best place to point out that diphtheritic patches not unfrequently make their appearance on the inner surface of the cheeks and on the gums, especially in the neighbourhood of the pillars of the fauces, and sometimes at the margins of the lips; and, further, that Bretonneau has described an affection of the gums (frequently associated with distinct faucial diphtheria and evidently of the same nature) in which an abundance of rust-coloured tartar accumulates about the necks of the teeth, in association with marginal pellicular formations on the gums, and a tendency to the development of similar patches on those parts of the inner surfaces of the lips and cheeks with which the diseased gums are in contact. There is excessive fetor of breath and disposition to gingival hæmorrhage.

2. Extension of the diphtheritic inflammation along the œsophagus is not very common, nor is it attended with any marked special symptoms. Both difficulty and pain in swallowing, and complete and unconquerable anorexia, are not unfrequent accompaniments of severe cases of simple diphtheria, and hence would not be characteristic of this complication, although they would probably attend it.

3. Diphtheria of the air-passages constitutes one of the most frequent, and at the same time one of the most fatal, of the varieties of the disease. In some cases, no doubt, the larynx or trachea is the primary seat of inflammation and membranous exudation, the fauces remaining healthy.

Under these circumstances, croupy symptoms manifest themselves simultaneously with the first onset of febrile disturbance, and we have in fact a case of typical croup. In a much larger number of cases, however, the laryngeal mischief supervenes on ordinary pharyngeal diphtheria, the membranous inflammation extending from the one part to the other by continuity. But since in this case the preceding affection of the pharynx is often exceedingly slight, not to say trivial, and has very likely given little or no positive indication of its presence, the laryngeal sequence is very apt to be assumed to be the primary disorder; and, again, the case falls in with the classical descriptions of croup. In many cases, however, the pharyngeal affection is severe, and has been recognised before the symptoms of croup appear. Here the sequence of events is obvious.

Thus, diphtheritic affections of the larynx and other air-passages either may be secondary to pharyngeal diphtheria, or may commence in the larynx, trachea, or possibly even bronchial tubes, and then either remain limited to these parts or spread upwards to the pharynx. Under any circumstances the symptoms resulting from the laryngeal or tracheal affection are of the same kind, and of extreme gravity. The child (for although membranous croup occurs in adults, it is mainly children who suffer) is first attacked with a frequent, short, dry, perhaps metallic, cough and slight hoarseness of voice—symptoms in this affection of the worst omen, even if in other respects he appears, as he often does, to be fairly well. But soon, some difficulty of breathing supervenes, commencing usually in the night. The symptoms now rapidly increase in severity; breathing (inspiration more than expiration) becomes noisy, sibilant, stridulous, or metallic, especially after an attack of coughing; the voice grows hoarser and weaker, or fails; the cough gets less frequent but more severe—paroxysmal, suffocative, harsh, unmusical, and wheezy, or far less commonly hard and metallic; and during the paroxysms the child tosses itself about, sits up, clutches whatever is near it, throws its head back, opens its mouth, dilates its nostrils, and struggles for breath; the general surface and especially the face become livid, the eyes staring, and the expression one of intense anxiety. Even now, in the intervals between the paroxysms of cough, the child often assumes a fallacious appearance of ease and comfort; the breathing may be a little quickened, and, unless under excitement, attended with little noise; and the best hopes of recovery may arise. But the paroxysms return and increase in frequency and severity; until at length, overcome by his exertions and progressive suffocation, the patient passes into a condition of combined coma, asphyxia, and prostration, in which he dies. Death takes place sometimes in a few hours, rarely later than the fourth or fifth day after the commencement of symptoms. In adults the course of the disease is usually not so acute. During the progress of the attack, the respirations increase in frequency; the pulse becomes small, weak, and rapid; the surface, especially that of the extremities, gets cold; and perspirations break out. Further, consciousness remains for the most part unimpaired almost to the close. The symptoms above detailed are clearly referrible

to the gradual growth and extension of false membrane in the larynx and trachea, and are occasionally relieved by their expulsion in the act of coughing. The paroxysmal cough is probably dependent chiefly on the occasional blocking up by mucus of the narrowed rima glottidis or trachea, and on spasm. The spread of the false membrane throughout the bronchial tubes, and the supervention of lobular pneumonia, are indicated mainly by rapid advance of lividity and asthenia, increasing imperfection of the respiratory acts, with falling in of the lower ribs and intercostal spaces during inspiration, inefficiency and feebleness of cough, and suppression of the auscultatory phenomena of the lungs. Emphysema of the connective tissue of the neck, head, and thoracic parietes, is occasionally developed.

4. Extension of the diphtheritic process to the nose, or the deeper tissues of the neck, constitutes an essential feature of the so-called 'malignant' form of diphtheria, and indicates severe concurrent constitutional poisoning and an almost certainly fatal issue. Malignant diphtheria often comes on with no more severe symptoms than those which attend the commoner forms of the disease; and even when local signs indicate the course the malady is taking, and the observant physician foresees and dreads the impending change, there is frequently nothing in the patient's condition to alarm himself or his friends. The spread of the disease to the nose is indicated by catarrhal symptoms, by redness and soreness of the nostrils, and by the discharge of mucus, frequently attended early with some degree of epistaxis, and, ere long, with a copious flux of bloody ichor. At the same time the lacrymal ducts become involved, the escape of the lacrymal secretion by the puncta is arrested, the eyes water, and occasionally false membranes form on the conjunctivæ. On inspection of the anterior or posterior nares the existence of the false membrane in the nose will probably be clearly recognised. The extension of the inflammation in depth is shown, partly no doubt by progressive enlargement of the tonsils and thickening of the soft palate and uvula, but more especially by rapid increase in size of the lymphatic glands about the angles of the jaw, and by infiltration with inflammatory products of the connective and other tissues which intervene between them. By these processes very considerable general tumefaction is produced; extravasations of blood and suppurating cavities appear here and there in the substance of the mass; ulceration or gangrene occasionally takes place at the mucous surface; and the cutaneous aspect, either uniformly or in patches, becomes brawny and congested or livid. In malignant cases, anæmia and prostration come on with great rapidity; the pulse early becomes quick, irregular, extremely small and feeble, and the surface cold; hæmorrhage frequently takes place from the mucous orifices, and petechiæ and vibices appear beneath the skin; the patient is restless and occasionally delirious; and death results from asthenia.

5. Although, in the vast majority of instances, diphtheria commences either in the pharynx or in the mucous cavities which communicate directly with it, cases are occasionally met with (especially during epidemic

outbreaks and amongst the members of infected households) in which the diphtheritic inflammation and pellicular formation first make their appearance in some other region—occasionally in the vulva or vagina, on the glans penis and foreskin, at the anus, in the external auditory meatus, or on excoriated or raw cutaneous surfaces. The local changes here are identical with those occurring in the more usual seats of the disease; the redness of the affected part is more or less vivid and intense, especially in a narrow zone circumscribing the adherent pellicle; the pellicle is white, buff, grey, or black, not unfrequently looking like an eschar, and adherent to the surface; and (when the skin is the part involved) its extension is attended with the formation of vesicles at the margins, which run together and lead to the development of spreading excoriations which presently get clothed with the enlarging pellicle. Just as in many cases of primary pharyngeal diphtheria false membranes appear after a while on various parts of the surface of the body, so, in the cases now under consideration, it is not uncommon to find the pharyngeal mucous membrane ultimately involved.

There are two or three important points in relation to diphtheria which have been either passed over, or merely touched upon, in the foregoing account, but must not be forgotten. The temperature of diphtheria is never a characteristic feature, and is rarely high. In some, and even severe cases, it scarcely at any time exceeds the normal; generally, however, there is distinct elevation during the first day or two; and occasionally (but more particularly in those cases in which the larynx and trachea are implicated) the temperature rises in the course of the disease to  $106^{\circ}$  or  $107^{\circ}$  and upwards. The urine in a large proportion of cases (one-half or two-thirds, according to different observers) becomes albuminous at an early date, the amount of albumen being sometimes very great. Occasionally, and more especially in malignant cases, there is hæmaturia. Under the microscope will be found, in the former case hyaline and granular casts; in the latter blood more or less modified in character. These conditions of the urine are rarely of long duration, and scarcely ever usher in dropsy, uræmia, or permanent lesion of the kidneys. Urea is excreted in excessive quantities during the progress of the disease, and diminishes during convalescence. Inflammation now and then extends from the throat to the ear, and may produce suppuration and other serious lesions in that organ; and occasionally it spreads from the conjunctiva to the cornea, causing opacity, ulceration, and perforation. Delirium is of unusual occurrence, and generally forebodes a fatal issue.

The duration of diphtheria varies widely, and relapses occasionally take place. When the disease ends in convalescence it rarely exceeds a fortnight, and it may be as little as a week. Death occurs at very different periods, which, however, are largely determined by the nature of the lesions inducing it. It may take place within the first twenty-four hours, or as late as the end of the second week, or at any intermediate period. The causes of death have been sufficiently considered. The mortuary rate of diphtheria is high; but it is impossible to make any

exact statement on this point ; for while in some epidemics undoubtedly many mild cases occur of which a large proportion are never suspected to be diphtheria, in other epidemics the fatality of the disease is frightful. The most fatal forms of diphtheria are those in which the air-passages are affected, especially in children, and those which have been spoken of as malignant.

Diphtheria does not always cease with apparent convalescence. But in many cases, after a period which varies between a week or two and two or three months, the patient is attacked with creeping paralysis, which, beginning as a rule in the fauces and eyes, slowly pervades the rest of the body, more especially the extremities, involving not only motion but also sensation, and occasionally even the special senses. The paralysis is for the most part symmetrical in distribution, and tends to get well in one part while it is extending elsewhere.

Usually the first, and maybe the only, part affected is the soft palate : the patient ' speaks through his nose,' when he swallows food it is apt to pass into the posterior nares, and on examination the velum is found more or less pendulous, motionless, and insensible. About the same time, or perhaps a day or two later, the eyes begin to suffer. For the most part the power of accommodation becomes impaired or lost, owing to paralysis of the ciliary muscles, and sight fails for near objects. Occasionally a squint becomes developed, or nystagmus, or both. Then paralysis of the extremities comes on, beginning sometimes in the hands, but more commonly (it is said) in the feet. He first complains of numbness, tingling, and clumsiness in the affected parts. Then gradually the symptoms spread and become more profound, until probably the arms and legs are involved in their whole extent, and power and feeling are more or less completely lost. The tendon reflexes, especially those in the legs, are usually exaggerated at the beginning, but in the course of a week or two become wholly lost. And not unfrequently the muscles before long manifest the ' reactions of degeneration ' and waste in a greater or less degree. In order to complete the picture of an ordinary case, it may be added that patches of anæsthesia are apt to appear in various parts of the body, mainly in the middle line ; and more especially at the tip of the nose, across the upper lip, at the point of the tongue, on the chin, involving the organs of generation, and about the anus.

Many other paralytic phenomena, besides those above discussed, are liable to arise during the progress of the case. Sometimes the fauces or larynx, or both, become anæsthetic or paralysed, so that the patient has difficulty in deglutition, fluids tend to find their way into the larynx, and the voice becomes impaired or lost. Sometimes the paralysis extends to the muscles of mastication, articulation, or expression. Sometimes the patient suffers from amblyopia or amaurosis, or from deafness, or from impairment or loss of taste or smell. Not unfrequently the trunk muscles become affected, more especially the intercostals or the diaphragm, and shortness of breath with (in the latter case) difficulty in straining at stool results. Further, the rectum and bladder may share

in the general paresis; and there may be complete loss of sexual power and appetite.

Occasionally hyperæsthesia and neuralgic pains replace, or attend, the paralytic phenomena; and occasionally also there is tenderness along the nerves or in the muscles. Tremors now and then occur in the affected limbs. We have pointed out that diphtheritic paralysis tends to be symmetrical; but it must be added that the symmetry is not absolute, and that paralysis of separate nerves (as of the facial) may take place.

Diphtheritic paralysis varies in duration, but generally ends in perfect recovery in the course of two or three, or at the outside four, months. It is far, however, from being devoid of danger; and, among children especially, the mortality from it is considerable. Death may result from inability to swallow, from the accidental intrusion of foreign matters into the larynx, and especially from asphyxia due to paralysis of the respiratory muscles, or from failure of the heart, or syncope. Occasionally death is due to convulsions or coma. There is reason to believe that in rare cases the paralysis, associated with wasting of the limbs, becomes permanent.

In speaking of diphtherial albuminuria we remarked that it is usually one of the early phenomena of the disease. But it sometimes comes on again, or for the first time, during the paralytic stage.

*Morbid anatomy and pathology.*—The morbid changes attending diphtheria are almost limited to the circumscribed inflammations which have already been discussed. In most cases the affected parts are congested, swollen, and infiltrated with leucocytes and other inflammatory matters; and, when the inflammation extends deeply, extravasations of blood and foci of suppuration, terminating in distinct abscesses, occasionally appear. The inflamed surface secretes abundant thin mucus, and soon an opaque layer forms upon it. This increases by additions to its under surface and to its edges, and is attached to the subjacent mucous membrane, partly by general adhesion, partly by prolongations into the mucous and other follicles. In the first instance it consists only in the inflammatory proliferation of the epithelial cells, which become cloudy and are apt from the shrinking of their protoplasm to assume a stellate form, the resulting interstices being probably occupied by mucus. This appears to be its permanent condition in the pharynx. But in the air-passages a fibrinous exudation takes place before long at the surface of the membrana limitans, between it and the modified epithelial layer which it displaces, and coagulating there forms a more or less distinctly laminated network of fibres which entangles leucocytes but very rarely distinct epithelial elements. Under these circumstances the superficial cellular lamina undergoes gradual disintegration and disappears, and thus the diphtheritic membrane at length becomes purely fibrinous. Many lowly vegetable organisms have, as might be supposed, been detected in it. It is not clear that any of them can be justly regarded as specific. Heuter, Oertel, and some other observers, however, maintain that the contagium of the disease consists in certain forms of bacteria, which they describe as existing in great abundance not only in the diphtheritic exudation,

but in the lymphatic spaces of the subjacent corium. The membrane varies considerably in thickness and consistency, and, when very thick, its superficial parts are apt to be pulpy or flocculent. Its detachment often exposes an excoriated surface, and sometimes distinct ulceration. Occasionally gangrene occurs. We have pointed out the localities in which diphtheritic membranes are chiefly formed. It remains to say that, when they extend into the nose or larynx, they adapt themselves accurately to irregularities of surface, and form complete solid casts of such diverticula as the sacculi laryngis; and that, when they involve the bronchial tubes, they sometimes extend to their finest ramifications, forming arborescent laminated casts. It is mainly when the air-passages are invaded that collapse of lung and lobular pneumonia take place, and, in children, interlobular emphysema, going on, it may be, to general emphysema. The only other organs ordinarily presenting obvious morbid changes are the kidneys. These may be enlarged and somewhat pale, and on microscopic examination may present granular or fatty deposits in the renal cells, with hyaline casts occupying the canals of some of the tubules. In malignant cases, besides intense local mischief, hemorrhages take place beneath the serous and mucous membranes and into the substance of the lungs, heart, kidneys, and other organs; and sometimes the muscular tissue of the heart presents granular or fatty changes. The blood has been said to be distinctly modified in character; but this is certainly not always the fact; and even in the worst cases fibrinous clots may be discovered in the cavities of the heart.

That diphtheria, like the exanthemata, is a specific disease affecting the system generally, can scarcely be doubted; its symptoms and progress, and especially its paralytic sequelæ, all attest the truth of this view. There may still, however, be a doubt as to whether the primary diphtherial patch, the formation of which attends the first onset of the disease, is a localised outcome of the general disorder and analogous therefore to the rash of variola; or whether it is to be regarded as the direct result of inoculation, and analogous therefore to the inoculated variolous pustule. In what way the diphtherial poison induces paralysis is a problem which has not yet been conclusively solved. Congestions and hemorrhages have been found in various parts of the brain and cord, and in the roots of the spinal nerves. But in many cases no changes whatever have been detected. On the whole it seems probable that a wave (so to speak) of slight inflammatory, or other morbid, process slowly traverses the medulla oblongata and the cord, and in some cases also the nerves in relation with the paralysed districts.

*Treatment.*—The treatment of diphtheria is a subject of much interest and importance, and not the less so that great variety of opinion has prevailed even in regard to points of vital moment. One of the most remarkable features in the disease is its tendency to produce anæmia and exhaustion, and death by asthenia. Such being the case, it is scarcely necessary to say that depletory measures cannot be adopted without grave risk. Indeed it is now almost universally admitted that the general

treatment should be directed to the maintenance of the bodily powers. To this end, nourishment by appropriate kinds of food, and the use of such tonic medicines as the patient can bear, must be firmly enforced. The liquid or pulpy foods generally administered in acute febrile disorders are suitable here; for medicine it is fashionable to prefer the solution of perchloride of iron, and doubtless the preparation is a valuable one; but there is no reason why other preparations of iron should not be given, or for the avoidance of quinine and other vegetable tonics. By some, chlorate of potash, or this with the addition of small quantities of hydrochloric acid, is strongly advocated. For local treatment of the affected mucous membrane various agents have been proposed. Bretonneau, and Trousseau following him, strongly recommend the free application of undilute hydrochloric acid; others prefer strong solution of nitrate of silver or of bicarbonate of soda, or pure tincture of the perchloride of iron, or creasote. Again, other practitioners (ourselves among the number) regard the use of strong caustics as useless, if not injurious, and prefer to wash out the throat or have it gargled with solution of chlorate of potash, chlorinated soda, carbolic acid, thymol, permanganate of potash, salicylic acid, or other antiseptic or cleansing fluid; and undoubtedly the administration of ice in small lumps is in many cases very grateful. Remedies to the nose must be applied either in the fluid form by means of a syringe or nasal douche, or as a powder by insufflation. The larynx must be treated, either by insufflation, by 'swabbing,' or by the use of the vaporising apparatus under the guidance of the laryngoscope. Emetics, which were formerly and are still often given for their supposed specific effects on inflammations of the respiratory mucous membrane, have been regarded as remedies of the utmost importance in croup, and therefore in all cases in which the diphtherial membrane tends to pass into the larynx. They are sometimes useful, indeed, but chiefly if not entirely by the mechanical influence of the vomiting which they induce, in promoting the expulsion from the larynx and trachea of the mucus, or even of the false membrane, which obstructs them. They must, therefore, be regarded mainly as local remedies. Of emetics it is best to give those that act rapidly without inducing much depression; for these reasons, large doses of ipecacuanha or of sulphate of copper are preferable to equivalent doses of antimony.

As soon as distinct implication of the mucous membrane of the larynx or trachea occurs, the question of the performance of tracheotomy will necessarily and properly present itself. The extreme fatality of croup if left to itself, the little influence which drugs exert over its progress, and the fact that death is in the great majority of cases directly due to the affection of the larynx and trachea, render in many cases the opening of the trachea our only hope. It is doubtless generally difficult to decide at what moment the operation becomes imperative. Here the physician must do what he thinks best according to his own judgment, bearing in mind, however, that it is much better to perform the operation too early than late, and that he ought not to be deterred from doing it by the

occurrence of one of those deceptive intervals of calm and tranquil breathing which are so common even while the disease is hastening to its fatal issue. Further, it is better to operate even when life seems ebbing away, or the patient is moribund, and in the face of every discouragement, than to let him die suffocated before one's eyes without making an effort to save him. Trousseau's vast experience of this treatment of croup gives an average of one successful operation out of four; he points out, however, that tracheotomy in children under two is scarcely ever successful. Other writers (chiefly foreign) record results at least equally encouraging.

In the treatment of convalescence, and in that of the consecutive paralysis, all efforts should be directed to improve the general health of the patient and to give him strength. With these objects, change of air, tonics (especially quinine and iron), good diet, and a fair proportion of stimulants, are most important. Other agents may be serviceable in promoting the cure of the paralysis, especially strychnia, galvanism, and friction.

Lastly, looking to the established fact that breaches of the cutaneous surface have a great aptitude to become the seat of diphtherial inflammation, it should be regarded as a fundamental rule never to employ blisters or other remedies calculated to produce sores.

---

## XVIII. ENTERIC FEVER (*Typhoid Fever. Abdominal Typhus*)

*Definition.*—A febrile disorder, characterised by an inflammatory affection of the agminated and solitary glands of the intestines, gastro-intestinal disturbance, and a peculiar rash.

*Causation and history.*—Enteric fever is a disease of worldwide prevalence, occurring for the most part in an endemic form, but occasionally assuming the proportions and the behaviour of a genuine epidemic. It seems to have no special connection with overcrowding, poverty, or ill-health, and indeed to attack the denizens of town and country, rich and poor, healthy and ailing, with singular impartiality. Sex is without influence over it; but children and young persons are much more liable to it than adults, and these than such as are of advanced age. Dr. Murchison's investigations show that more than half the total number of cases admitted into the London Fever Hospital during ten years occurred in persons between the ages of fifteen and twenty-five; more than a fourth in persons under fifteen; one-tenth in persons between twenty-five and thirty; and that from the latter age onwards the numbers rapidly diminished. Considering, however, how few children attacked with enteric fever are likely to become hospital patients, it seems not improbable that the tendency to contract the disease is pretty nearly equal at all ages up to about twenty-five, and that from that epoch it rapidly and uniformly diminishes. Undoubted cases have been recorded at various ages,

between seventy and ninety. Dr. Murchison also shows from the records of the Fever Hospital that enteric fever prevails chiefly in October, November, September, and August, and that it is at its minimum in April, May, February, and March; and he confirms the general belief that its prevalence is augmented by excessive heat of weather, and diminished by continuous low temperature. There is reason to believe that persons newly arrived in districts in which enteric fever is endemic are more likely to take it than those who have resided there for some time.

The confusion which prevailed up to within a recent period in regard to typhus and enteric fevers rendered any exact knowledge of their causation impossible. Since, however, they have been recognised as distinct and specific diseases, much light has been thrown upon the subject. It has been proved, indeed, apparently beyond all cavil, that enteric fever is above all fevers the fever of faecal decomposition; that it occurs only among those who are exposed to the influences of defective drains or foul and overflowing cesspools, especially when these are so situated as to pour forth their fetid gases into the interior of houses, or to contaminate by their emanations, their soakage, or their leakage, water and other articles used for food. In opposition to this view, it has been asserted that persons who work in the sewers are never attacked with enteric fever; but even if this were the fact (which it is not), it would weigh nothing against the positive evidence on the other side, which has been furnished of late years by repeated scientific investigations into the causes and circumstances of local outbreaks of the disease all over the country. Also, several local outbreaks of enteric fever in Switzerland have been traced to the eating of the decomposing flesh of unhealthy calves.<sup>1</sup> But whether the calves were themselves suffering from enteric fever, or their flesh had derived its infectious qualities from some other source, is at present uncertain. The subject of its etiology is not exhausted in the above remarks. It is admitted by most physicians that enteric fever is not, in the usual sense of the term, markedly contagious, and that it is seldom or never conveyed from one person to another person by the emanations from the skin or by the breath. It rarely, if ever, spreads from one patient to another in a hospital ward. But attendants on the sick occasionally take the disease from them; and it is certain that the immigration of a patient, suffering from enteric fever, into an uninfected locality not unfrequently leads to an outbreak there. We have pointed out that the virus seems not to escape with the breath or from the skin; and it must be added, that if it escapes with the faeces in an active form it is difficult to understand how the nurses, and other persons brought into relation with the sick, so constantly escape infection. It has been observed, however, over and over again, that the faeces, which are probably at first wholly ineffective, become in the course of putrefaction, virulent in a high degree, and impart their infectious properties largely to the contents of cesspools and sewers, and thence to well and other waters, with which the former happen to communicate. In many cases, indeed,

<sup>1</sup> Dr. Cayley, Croonian Lectures, *British Medical Journal*, March 20, 1880.

the source of an enteric-fever outbreak has been distinctly traced to the water of a well, into which there has been percolation from a neighbouring cesspool recently contaminated with the evacuations of a patient suffering from that fever; and occasionally, also, groups of cases seem to have been distinctly referrible to body-linen and bedclothes befouled with typhoid evacuations, which have been allowed to accumulate and remain unwashed. It seems clear, therefore, that persons suffering from enteric fever discharge in their fecal evacuations (as do cholera patients) some specific organised substance; which, after its escape from the body and under suitable circumstances, increases and at the same time becomes specially virulent, diffusing itself throughout the fluid media to which it gains access, and imparting to them its specific properties. The question then arises, Does the specific poison of this disease, which is certainly developed from the stools of patients suffering from it, also arise spontaneously, or rather independently of such stools? Dr. Murchison especially argues forcibly in favour of its origin independently of the disease which it generates. Dr. W. Budd and others argue with equal vehemence in support of the opposite hypothesis. We adopt the latter view, and, in accordance with it, regard the essential cause of enteric fever not as a mere inorganic or even organic result of decomposition, but (like other contagia) as an organised living particle which has special endowments and unlimited powers of multiplication; not as the product of healthy bowels or of ordinary decomposing ordure, but as a specific virus yielded by the bowels of patients suffering from enteric fever, and probably by them alone. A further question here presents itself—namely, By what route does the virus gain admission into the system? It is certain that in many cases it is received into the alimentary canal; it is thus that the disease is imparted by contaminated water, and by milk to which contaminated water has been added. It is generally believed also that it may be inhaled with the breath, and that it is thus that the effluvia of cesspools and drains act in producing the disease. On the whole there is reason to suspect that the virus in all cases enters the system at the surface of the alimentary mucous membrane, and that the intestinal lesions are to be regarded as points of inoculation.

One attack of enteric fever is believed to confer immunity against subsequent attacks. If, however, this be so, the immunity is much less perfect than in the case of the infectious fevers generally, for many second attacks have been recorded; and moreover, true relapses are far more common in this than in other allied specific disorders.

*Symptoms and progress.*—There is reason to believe that the incubative stage of enteric fever varies between about six and twenty-four days. The mode of attack and the initiatory symptoms of the disease present great variety. In exceptional cases its invasion is as sudden and well marked as that of typhus, the symptoms moreover resembling those of that disease. But much more commonly it comes on so insidiously, with undefinable feelings of malaise, or slight feverishness, or failure of appetite and strength, or some degree of gastro-intestinal disturbance, extending

over several days, that the patient is quite unable to fix the date of the commencement of his illness. During the early period of enteric fever, the patient suffers in a greater or less degree from the following symptoms :—Irregular chills and flushes of heat ; increased frequency of pulse, and elevation of temperature ; lassitude and aching in the limbs ; thirst, and loss of appetite, with morbid redness or coating of the tongue ; and headache or heaviness of the head, with tendency perhaps to drowsiness by day, to wakefulness, restlessness and dreaming, at night-time. Epistaxis is not uncommon. Vomiting and diarrhoea, with abdominal pain, and tenderness in the cæcal region, are generally associated with the above symptoms, and, though sometimes absent, are often the very earliest and generally the most striking of the phenomena which attend the earlier period of the disease. During the first week of the fever, although the symptoms gradually increase in severity, the patient is very often not confined to bed. At the beginning of the second week, however, unless the case be exceptional either in its mildness or in its intensity, the symptoms become more fully developed and assume a more characteristic aspect. The fever reaches its acme ; the skin generally is hot and dry, but liable to break out in perspirations ; the pulse still increases in frequency, as also do the respirations, and not unfrequently there is some degree of cough ; the tongue may continue clean or become coated with a moist fur, but generally, whether coated or clean, tends to get dry and to present cracks, mostly transversal, upon the dorsum ; the vomiting has very probably subsided, but thirst and anorexia continue, and there may be some difficulty in swallowing and speaking in consequence of soreness of the throat ; the patient sleeps badly ; and occasionally, but by no means in all cases, delirium comes on, especially at night time and between waking and sleeping. It is about this time, too, that the rash which is peculiar to the disease first makes its appearance. It consists in lenticular rose-coloured spots, distinctly elevated and sensible to touch, disappearing on pressure, and varying when fully formed from half a line to a line and a half in diameter. Though generally rising above the general level in the form of segments of spheres, they occasionally become vesicular in the centre and thus more or less distinctly acuminated. They are rarely numerous, and always appear in successive crops—those of each crop attaining their full development, and disappearing, in the course of two, three, or four days. Thus, spots of various ages are generally present, and intermingled at one and the same time. In perhaps one-fourth of the total number of cases no spots are ever discovered, and in the remainder their number may vary from a dozen or less up to many hundreds. They are chiefly developed on the chest, abdomen, and back ; but occasionally are observed on the face and extremities. At this time too the intestinal symptoms usually become pronounced ; the abdomen is tumid ; tenderness and pain manifest themselves more distinctly in the right iliac region, where also on pressure gurgling may be detected ; and the bowels become loose—open three, four, or a dozen times a day, and discharging liquid yellow stools which have been likened, not unaptly, to

pea-soup. The spleen too has become enlarged, and its edge will probably be felt below the ribs. From the condition above described the patient may gradually recover. But in a large proportion of cases he passes, in the course of the second week (probably towards its close), into a typhoid condition. The elevation of temperature continues; the rash still comes out; the diarrhœa persists; the tongue becomes dry and brown and traversed by deep fissures, the lips and teeth covered with sordes, the pulse quicker and more feeble; the general prostration increases; complaints of headache and pain cease; the mind grows dull and apathetic; drowsiness and delirium (sometimes violent, sometimes busy, sometimes muttering) supervene; and bed-sores tend to form. Blood, in greater or less quantities, is now not unfrequently passed with the stools. Finally, if the case be going on unfavourably, tremors, subsultus, and involuntary passage of the evacuations come on, the somnolence or delirium passes into coma, and death ensues. If, on the other hand, the case be likely to do well, convalescence commences usually in the course of the third or fourth week. The change is in general gradual. The fever abates, the pulse falls, the cerebral symptoms pass away, the tongue cleans, the appetite reappears, the diarrhœa ceases, and the strength returns. The progress of convalescence is, however, always slow, and the patient often does not regain his former health until after the lapse of many months. Occasionally, when convalescence seems to be fairly established, a relapse takes place, attended with the rash and all the other characteristic symptoms and phenomena of the disease. This may be in all respects more severe than the primary attack. A second relapse may follow.

The foregoing account applies, for the most part, fairly well to the ordinary run of well-marked, uncomplicated cases of enteric fever. No disease, however, is attended with greater variety of symptoms, or presents more frequent and greater departures from the typical character. It is desirable, therefore, to discuss briefly the various phenomena of the disease, and its varieties.

The pulse varies greatly in frequency. Occasionally, in very mild cases, it scarcely exceeds the normal throughout the whole course of the illness. In other cases, however, it mounts (in dependence very much on the severity of the case) to 90 or 100, and from this to 120, 140, or even 200, and becomes very feeble. It is generally quicker in the evening than in the morning, and in the typhoid stage than in the earlier period. Other things being equal, rapidity of pulse implies severity of attack. It is curious, however, that even during the presence of marked fever the pulse may at times sink below 50 or 60. In one of Dr. Murchison's cases it fell to 37.

The respirations are generally accelerated, especially with the advance of the fever, and not unfrequently some little cough is present. These symptoms are necessarily greatly aggravated when (as not unfrequently happens) bronchitis or pneumonia becomes developed. Then also the surface is apt to get dusky, and the local signs of the complication manifest themselves.

The character of the tongue varies. In some cases this organ remains almost normal throughout the illness, or is merely a little redder and drier than natural, or presents the slightest possible increase of epithelium only. More commonly it is covered, except at the margins, with a whitey-brown fur which tends to become dry; or it has a dry, glazed, morbidly red character; and in either case is apt to present transverse cracks which are often of considerable depth. The throat is not unfrequently congested and sore, and there may even be inflammation of the tonsils at an early period. Sickness is one of the most common of the initiatory symptoms, and is sometimes exceedingly severe. It may last throughout the whole illness. Thirst and loss of appetite are almost invariably present. Diarrhœa is seldom absent, and is often very severe. Not unfrequently it prevails from the beginning; but in many cases it does not come on till the second week, or even later; and sometimes there is constipation throughout, or the patient has an occasional loose stool only. The motions usually have the appearance and consistence of pea-soup, are alkaline, and offensive; in the course of the second, third, or fourth week they may contain blood. The progress of the fever is generally attended with abdominal pain, tenderness and gurgling in the right iliac fossa, flatulent distension of the belly, and manifest enlargement of the spleen.

In the early part of the disease the urine is scanty, dark-coloured, and of high specific gravity; later on it becomes pale and copious, and its specific gravity falls. There is almost always a large increase in the amount of urea and uric acid, especially at the commencement; and the chlorides are diminished. Albumen is not present in more than one-third of the total number of cases, and occurs for the most part in very small quantity and seldom before the third week.

The skin, though for the most part dry, is apt to become moist, especially in the morning; and during the latter part of the second, or in the third week, profuse perspirations may occur. The cheeks, especially after meals or during the febrile exacerbations, are often flushed. The rash, which has already been described, continues by successive outbreaks for one, two, or three weeks. During convalescence perspirations are often very copious, and sudamina generally appear on the chest.

The fever, as indicated both by the thermometer and by symptoms, is almost always of a remittent character, presenting morning falls and evening exacerbations. The temperature begins to rise about noon, and attains its maximum between 7 P.M. and midnight. After midnight it gradually falls, the lowest point being usually attained between 6 and 8 A.M. In uncomplicated cases these daily alternations are almost constant, the difference between the morning and evening temperatures varying from one to two or three degrees, or even more. The rise begins from the first day of illness, and gradually increases by daily waves until, on the fourth or fifth day or about the end of the first week, it attains its greatest elevation, which varies in different cases between 104° and 106°. From this period up to about the twelfth day there is but little change. Then,

if the case be mild, the morning falls become lower and of longer duration, to be followed shortly by a corresponding decline in the evening rises; and gradually, as convalescence becomes established, the morning and evening temperatures approximate until they attain their normal level, or even sink below it. If, on the other hand, the case be severe and the commencement of convalescence be delayed, the temperature still continues high, and the morning remissions often become less marked than they had been. Again, if in the course of the disease serious complications arise, the usual course of the thermal variations is modified; and occasionally, even from the beginning, and throughout the first week or two, the temperature is almost uniformly high. Profuse diarrhœa, epistaxis, or intestinal hemorrhage causes the temperature to fall; as also does the condition of collapse, however produced. Pneumonia makes the temperature rise, and modifies its diurnal variations. Sometimes it rises before death to  $108^{\circ}$  or even to  $110.3^{\circ}$  independently of complications (Wunderlich).

As regards the organs of sense: singing in the ears and deafness are not uncommon; the conjunctivæ are seldom congested; the pupils are usually dilated; epistaxis is of frequent occurrence. Most patients complain, at the beginning of the disease, of giddiness and headache, and of pain and sense of lassitude in the limbs. There is often wakefulness at night; sometimes, on the other hand, there is somnolence, and this not unfrequently precedes delirium. Delirium is a variable symptom; in many cases it never occurs; in many it is slight, and shows itself only between waking and sleeping; in severe cases it usually comes on about the middle or end of the second week, and is then apt to vary in character and duration. It may present all the characters of the delirium of typhus; but, as Dr. Murchison remarks, it is more frequently of the violent and noisy kind than in that disease. In rare cases the invasion of the fever is attended with maniacal excitement. Coma occasionally supervenes before death. Epileptiform convulsions are not usual, but are more common in children than in adults; they may appear early in the disease, but generally come on late, and frequently prove fatal. Muscular weakness is always present, but is not so marked as in typhus; nevertheless, in the later stages of severe cases, tremors and subsultus are common. Occasionally there is muscular rigidity.

Enteric fever presents itself in many forms, and has been and still is frequently confounded with other diseases. It is especially important to know that, for the most part, cases of so-called 'infantile remittent fever,' 'worm fever,' 'gastric fever,' and 'bilious fever' are cases of this affection. In the mildest form of the disease the patient perhaps complains only of slight feverishness and weakness, with loss of appetite and diarrhœa or irregularity of the bowels, and probably goes about his ordinary avocations, or at all events does not take to his bed, and, if no complication supervenes, recovers at the end of three or four weeks. In other cases the disease is much more severe in character, and its progress is more or less distinctly in accordance with the account we have already

given ; the attack is one of well-marked enteric fever, but varies according to the relative prominence of certain of the symptoms, such, for example, as vomiting, diarrhœa, thoracic symptoms, hemorrhage, and delirium. In other cases, again, the attack is from the beginning of exceptional severity, and, as in analogous cases of scarlet fever and other like affections, the patient dies, poisoned apparently and in a state of collapse, within the first week, sometimes on the first or second day.

Much of the danger which attends enteric fever depends on the complications which arise in its progress. The most important of these are intestinal hemorrhage, perforation of the bowels with peritonitis, and pneumonia or bronchitis.

It has already been pointed out that intestinal hemorrhage is not unfrequent. It may occur at almost any period of the disease, but is most common from the middle or end of the second week to the end of the fourth. It may be due, in cases where there is a general hemorrhagic tendency, to oozing from the mucous membrane ; but far more commonly it takes place from the surfaces or edges of the intestinal ulcers. It has no necessary connection with the extent or size of the ulcers, or with the presence or absence of diarrhœa, or indeed with the mildness or severity of the patient's previous symptoms. The hemorrhage may be scanty, or so copious as to cause speedy death by syncope ; and the blood which escapes may be fluid or clotted, black or of the normal colour of blood.

Peritonitis is one of the most frequent causes of death in enteric fever, and, like intestinal hemorrhage, has no necessary dependence on either the severity of the case or the urgency of diarrhœa. In the vast majority of cases it is due to perforation of the bowel in the floor of one of the intestinal ulcers, and is therefore sudden and unexpected in its onset. Not unfrequently perforation occurs in patients who have never taken to their beds ; who are then seized, without warning, with intense abdominal pain, tenderness and distension, together with vomiting, collapse, thoracic respiration, and other symptoms of acute peritonitis. In such cases the nature of the complication is manifest. When, however, it takes place in patients who are already in a typhoid condition, the indications are apt to be overlooked. Yet, even in these cases, there may be more or less evident abdominal pain and other local signs of peritoneal inflammation ; but very often the diagnosis must be made to rest mainly on the sudden supervention of collapse, with first a fall and subsequently a rise of temperature, increased rapidity and feebleness of pulse, hurried and thoracic respiration, duskiness of surface, copious perspirations, and flatulent distension of the abdomen or tympanites. Indeed it may be said generally that a sudden occurrence in the course of enteric fever of symptoms of intense collapse, even when no direct evidence of abdominal inflammation is present, points to perforation. Perforation of the bowel may occur in patients of all ages, but is more common in males than in females. It cannot take place until ulceration has commenced, and, as might be supposed, is more common when ulceration is advanced than when it is beginning. Hence, although it occasionally happens during the second

week (more especially towards its close), it is much more common during the third, fourth, and fifth weeks ; and, indeed, all risk has not ceased until the expiration of two or three months. It may arise, therefore, during the period of convalescence, and even after apparently complete restoration of health. Death almost invariably follows this lesion ; and generally occurs within a couple of days, sometimes in the course of a few hours. But occasionally life is prolonged for a week or two ; in which case the peritonitis becomes circumscribed and an abscess forms. A few cases of recovery after the evacuation of such an abscess have been recorded. Dr. Murchison calculates that no less than one-fifth of the total number of deaths from enteric fever are due to perforation of the bowel.

Bronchitis is often present in a slight degree ; but occasionally it gets severe, and may be so at any stage of the fever. The symptoms of bronchitis are then added to those of the primary disease and mask them. So pneumonia, mainly lobular, may creep on insidiously at any time, but most commonly appears during the third or fourth week. It is usually connected with the hypostatic congestion of the lungs which is generally present in a greater or less degree ; and hence occupies mainly the back and basal portion of one or both lungs, and may fail to be detected unless the attention of the physician be specially attracted by the presence of symptoms indicating thoracic mischief. Pleurisy ending in empyema is also not unfrequent.

Many complications and sequelæ are described besides the above ; but they are, for the most part, unimportant or rare or not specially characteristic. We will enumerate a few of the more important. *Ulceration of the larynx or trachea ; thrombosis of the veins*, especially in connection with the lower extremities, leading to œdema ; *bed-sores* on the sacrum and other parts exposed to pressure or irritation ; *gangrene of the mouth (noma)*, *ears, penis, vulva, feet, cornea*, and especially of parts to which blisters have been applied, or which are already inflamed from other causes ; *inflammation of the parotids ; periostitis or acute necrosis ; imbecility, mania*, or other mental disorders ; *prolonged marasmus* ; and *tuberculosis*. Pregnant women not unfrequently abort. But neither pregnancy nor parturition appears materially to interfere with the prospect of recovery.

There is probably no other disease in which death threatens from so many quarters, and in which it may occur at such diverse and unexpected times. It is due immediately either to asthenia, asphyxia, or coma, or to combinations of these. It may happen early in the disease, mainly from the intensity of the attack ; in which case there is generally more or less pulmonary congestion. But it more commonly occurs later, either from pneumonia or other pulmonary complication, from perforation and peritonitis, from intestinal hemorrhage, or from coma coming on in the course of typhoid symptoms. Again, it may ensue during the period of convalescence, from one or other of the sequelæ of the disease, or from sheer exhaustion. Enteric fever in hospital practice is fatal in about the same

proportion as typhus—at the rate, namely, of about 15 or 16 per cent. But when we consider how large a number of mild cases occur, which are not only never admitted into hospital, but not even recognised, it becomes obvious that the proportion of total deaths to total attacks must be much smaller than the above figures imply. Excepting childhood, the percentage of mortality varies little with age; but, on the whole, the statistics of the London Fever Hospital show that the death-rate is less below the age of 20 than in the later periods of life, and that it is highest in patients above 50. Young children seldom die of the disease.

It is not generally difficult to distinguish between a case of enteric fever and one of typhus. The main clinical distinctions are furnished: first, by the invasion, which is generally sudden in typhus, insidious in typhoid; second, by the rash, which is abundant, general, and of nearly simultaneous origin in typhus, scanty and coming out in successive crops in typhoid; third, by the abdominal symptoms, which in typhus are usually vague, but in typhoid comprise the discharge of liquid yellow stools, intestinal hemorrhage, pain and tenderness in the cæcal region and tympanites; fourth, by the temperature, which does not in typhus present the gradual rise with regular diurnal variations which are so characteristic of typhoid; and, fifth, by the mode of convalescence, which is by crisis and rapid in typhus, but slow and followed by long-continued debility in typhoid. Many other distinctions of secondary value might be adduced. But it must not be forgotten that all may fail us, and that the discovery of the typical intestinal lesions after death may alone reveal the nature of the case which has been under treatment.

*Morbid anatomy.*—Enteric fever is always attended with characteristic anatomical lesions, affecting the solitary and agminated glands of the bowels and the mesenteric glands in direct relation with them. These lesions consist in an apparently simple hyperplasia of the glandular elements, in virtue of which the organs undergo rapid enlargement, and then either slowly subside, reverting to their normal condition, or undergo softening, suppuration, ulceration or gangrene. Under the microscope the lymphatic corpuscles are found to be increased in number; and frequently hypertrophied or giant cells, containing groups of small corpuscles in their interior, may be discovered among them; later on the cells get granular and fatty, and break down into a granular detritus. The morbid process appears to begin with the first symptoms of the patient's illness; at all events, it has been found well advanced in those who have died during the first few days.

The intestinal lesions are in many cases limited almost entirely to the agminated glands, of which sometimes two or three only, sometimes all, are involved. These gradually swell until they form oval plates from a line to  $\frac{1}{3}$  inch thick, which present a tumid margin, a reticulated or foveated but oftener more or less mammillated and smooth surface, and a consistence which is sometimes softer but more often denser, though more friable, than natural. They generally attain their full development by the ninth or tenth day—sometimes a day or two earlier, sometimes

a day or two later. And then they either undergo slow resolution or proceed to ulceration. The latter process may commence from the surface at numerous points, and thence gradually invade and destroy the whole of the diseased mass; or, as more frequently happens, the patch sloughs at once in the greater part or the whole of its extent. The resulting slough, which probably from bile-staining soon assumes a yellow or brown hue, becomes soft, spongy, and tumid, and separated by a line of demarcation from the still living tissues, and after a short time comes away either in mass or in successive fragments. The separation of the sloughs generally occurs between the fourteenth and twenty-first days, but may not be fully completed for another week. The resulting ulcer varies in character. Usually its form is oval or round; its margin thick and vertical, as if made by a punch, and congested; its floor pretty smooth and formed of the submucous tissue. Sometimes, however, the edge becomes undermined, and then perhaps intensely congested, and the floor irregularly excavated and flocculent, and formed partly of the exposed muscular coat, partly, it may be, of the peritoneal membrane only. Cicatrisation does not usually begin before the end of the third week, and probably as a rule is completed in about a couple of weeks more. But the process may be delayed, either from mere sluggishness, or in consequence of a kind of phagedænic extension of the ulcer, or by other circumstances, and hence may not be accomplished under two or three months. The cicatrices rarely if ever lead to serious contraction.

The typhoid process as it affects the solitary glands is precisely similar, excepting that the resulting tumours are much more numerous and much smaller—generally about the size of half a pea; and that, on the one hand resolution without ulceration is more common, and on the other the ulcers which form are of insignificant dimensions and tend to heal more rapidly.

The morbid process, whether it affect only the agminated glands or involve the solitary glands as well, is always most extensive and advanced in the ileum immediately above the ileo-cæcal orifice; whence in both of these respects it gradually diminishes upwards. The solitary glands are rarely affected to a greater distance than two or three feet above the valve; Peyer's patches seldom above the lower half of the ileum. The disease implicates the solitary glands of the large intestine in about one-third of the fatal cases, and is always most advanced in the cæcum, rarely extending below the ascending colon. Perforation takes place only in those ulcers which have already destroyed the muscular wall. But when the floor is formed of peritoneum only, it sometimes happens that local peritonitis occurs and causes adhesion between the affected portion of bowel and some neighbouring organ, and thus averts the impending catastrophe. The actual perforation may be due to the forcible separation of such adhesion; but more commonly, probably, it is the result of the simple accidental laceration of the softened and unsupported serous covering. It occurs in the great majority of cases in the lower two feet of the ileum; but it has been met with at least six feet above the ileo-cæcal

valve, and more rarely in the cæcal appendage or in the colon. The peritonitis which results is in the first instance always general; but not unfrequently, when the rupture is small and but little fæcal matter has escaped, this latter and the suppuration which it necessarily excites are found after death to be strictly confined by adhesions to a very limited space. It is this tendency to limitation which gives an element of hope in the treatment of these cases, and to which the very few recorded recoveries after perforation are due. Sometimes the laceration is so extensive that large quantities of fæcal matter are discharged at once into the peritoneal cavity.

The mesenteric glands, especially those connected with the lower part of the ileum, enlarge from the beginning with Peyer's patches, and sometimes attain the size of a walnut; they become soft and vascular, and at the end of ten days or a fortnight undergo resolution, or soften or suppurate. Under the latter circumstances they not unfrequently dry up eventually; sometimes, however, they induce peritonitis either by extension of inflammation, or by rupture into the serous cavity. Most other lesions in enteric fever, such as bronchitis, pneumonia, and pleurisy, have no specific character, and need no description. The spleen, however, is enlarged and congested; and it may be added that, when the patient dies during the ulcerative stage of the fever, the contents of the bowels are generally peasoup-like, and the large intestines inflated with gas.

Dr. Klein's<sup>1</sup> inquiries show that the smaller typhoid growths do not originate exclusively in the solitary glands, but that they often arise in the lymphoid tissue of the mucous membrane. He also shows that the typhoid process, whether taking place in the intestines or mesenteric glands, is attended with hyperæmia of vessels, increased development of lymphatic cells, and the development from these of giant cells, not unlike those of tubercle, and the rarefaction of the fibrous matrix. Further, he calls attention to the presence of a microscopical fungus, in connection with the specific intestinal lesions. This is characterised by a distinct mycelial growth, by greenish spherical bodies two or three times as large as blood-corpuscles, and by micrococci or spores of extreme minuteness which occur singly or in couples, strings, or irregular clusters. The fungus exists on the surface of the mucous membrane and within the tubular glands, but it pervades the epithelium and is especially abundant in the lymphatic spaces and channels, and in the small veins. Similar bodies are discoverable in the diseased mesenteric glands. Eberth also describes a particular form of bacillus as occurring in the intestinal lesions, in the mesenteric glands and in the spleen, and regards it as the specific cause of enteric fever.

*Treatment.*—Knowing as we now do the source whence the contagium of enteric fever enters the system, it becomes our duty, nor is it difficult, to adopt suitable precautionary measures both against the contamination of water and atmospheric air, and against the exposure of persons to the

<sup>1</sup> Report of Medical Officer of the Privy Council, New Series, No. vi., pp. 80 *et seq.*

influence of media thus contaminated. Whenever typhoid patients are under treatment their evacuations should be disinfected with carbolic acid, Condy's fluid, or chloride of lime, before they are emptied into the sewer or cesspool; and all articles of dress soiled by such evacuations should be similarly disinfected and washed. Water-closets and drains should be kept sound, clean, well flushed, and well ventilated, and all communications between drains and the interior of the house cut off by efficient traps. No water should be used for drinking or culinary purposes which has been exposed to sewage contamination; hence the water of superficial wells, especially if these be near cesspools or sewers, should be looked upon with grave suspicion, as also should the water derived from streams or ponds receiving drainage, and that from cisterns or butts communicating by waste-pipes with closet-drains. If such waters must be drunk, they should first be boiled and filtered. It must not be forgotten that milk, from the presence of water which has been fraudulently or otherwise added to it, has on many occasions been the vehicle for the communication of the disease.

Many remedies have been employed for the cure of enteric fever; amongst others mineral acids, antiseptics (such as chlorine, hyposulphites, carbolic acid, and creasote), and emetics. Other remedies have been used with the special object of reducing the fever—such are quinine in large doses (10 or 15 grains or more), salicylate of soda, actual refrigeration, and bleeding. The last practice has properly fallen into desuetude. The use of cold is often beneficial, especially in cases in which the temperature reaches or exceeds  $104^{\circ}$ ; it is best applied by means of baths, the temperature of which, to begin with, should be 10 degrees or more below that of the body, and then gradually reduced to about  $68^{\circ}$ , immersion being continued for about half an hour, or until the patient's temperature, as ascertained in the mouth or rectum, has become sensibly reduced, or shivering comes on. It is held that the reduction of the bodily temperature not only prevents the directly injurious influence of excessive heat, but arrests or modifies in a favourable sense the characteristic lesions of the disease; and there are many physicians abroad, and some in our own country, who maintain that by the habitual use of the cold or graduated bath in cases in which the temperature reaches  $103^{\circ}$  or thereabouts, the mortality of the disease is very largely reduced. If this treatment be adopted it should be begun early in the disease, and continued for so long as the temperature tends to rise injuriously: the number of baths administered daily ranging from one or two to seven or eight, according to circumstances. Even if not used continuously, cold bathing may be had recourse to from time to time when the temperature becomes excessive. Our own experience (which has not been very great) leads us to the belief that the persistent use of the graduated bath in this disease is attended with considerable risk, and especially that it is liable to induce fatal collapse and congestion of the lungs. Periodical sponging with cold or tepid water is probably always beneficial. But our chief aims in the treatment of enteric fever must be to guard against or neutralise the dangers

which threaten from so many quarters, and to relieve symptoms as they arise. The condition of the bowels must be carefully watched, and under no circumstances must drastic purgatives be employed. There is no harm, perhaps, in giving a mild laxative, such as castor-oil in small doses or rhubarb, during the first week of the disease and before ulceration has taken place, but even then it is generally sufficient, and on the whole certainly more safe, to employ enemata. Subsequently enemata only should be resorted to. When diarrhœa is present it should be restrained either by tannic acid, lead and opium, sulphuric acid, the compound kino powder, or some such remedy, or by opium or morphia suppositories, or enemata. Trousseau, Dr. George Johnson, and others think that the diarrhœa should not be restrained, regarding it as a curative effort of nature; that view, however, is not generally accepted, and is, we think, erroneous and dangerous. When hemorrhage from the bowels takes place, measures should be adopted to arrest it. Dr. Murchison has great faith in the use, under such circumstances, of turpentine, tannic acid, ergot of rye, or other forms of astringents. Hemorrhage occurring, however, during the first ten or twelve days is of little importance, and does not usually call for treatment. For the prevention of perforation, the avoidance of purgatives, the arrest of diarrhœa, and the maintenance of a quiescent condition of the bowels, are of extreme importance; it is further necessary to prevent the patient from using muscular exertion, and from taking articles of food likely to upset the bowels. If signs of perforation manifest themselves, our only hope lies in keeping the patient under the influence of opium or morphia—the dose and frequency of its administration being determined partly by the patient's age, but chiefly by its effects. Tympanites may be benefited by the use of stimulating enemata or hot fomentations to the belly. Sickness may be relieved by the use of lime-water and milk, bismuth or ice, or by counter-irritation. Pulmonary complications should be guarded against by the maintenance of an equable temperature, and by the avoidance of draughts. When present they must be treated on general principles. The great tendency there is to the formation of bed-sores makes it very important to keep the patient scrupulously clean and dry, to take measures to obviate and relieve pressure, and, if precursory redness make its appearance, to anoint the part with some stimulating and protective application. The diet should consist of fluid and easily digestible food given frequently (every hour or two), and in small quantities. The best aliments are milk, gruel, barley-water, rice-water, and such like; but arrowroot, sago, chicken-broth, beef-tea, and eggs are valuable. Stimulants are necessary when there is a tendency to collapse, when typhoid symptoms are present, or when there is great debility. In many cases, however, though their administration in moderate quantities can do no harm, they are by no means absolutely needed at any period of the disease.

Much care is necessary during convalescence. The great debility which endures so long demands the use of tonics and an abundance of nutritious food. But the liability to perforation of the bowel (which may

not cease until the end of two or three months) makes it specially important that the food should be easily digestible, and not of such a character as to derange the action of the bowels. For the same reason it is generally a good rule not to administer solid food until the temperature has fallen to the normal, and has continued normal or sub-normal for a week. Moreover, the liability to the supervention of pulmonary inflammation and of tuberculosis renders exposure and fatigue particularly dangerous. Change of air is often extremely beneficial.

## XIX. EPIDEMIC CHOLERA (*Asiatic or Malignant Cholera*)

*Definition.* An epidemic disease, of which the attacks are very severe and rapidly fatal, characterised by a copious discharge of watery fluid from the alimentary canal, suppression of the urine and other secretions, shrinking of the tissues, cramps, and extreme prostration.

*Causation and history.*—Epidemic cholera has been known in India for centuries, and probably from time immemorial. It is seldom entirely absent there, but at irregular intervals breaks out into widespread epidemics. The first Indian outbreak which specially interests us is that which, originating in the delta of the Ganges in the year 1817, soon ravaged the greater part of Hindostan, and during the next ten or twelve years spread over nearly the whole of Asia, including the Burmese Empire, China, Tartary, and Persia. In 1829 it commenced its progress through Tartary and Persia into Europe, and in that year it reached Orenburg. It then became temporarily arrested, but subsequently took a fresh start, and still travelling slowly westwards it appeared, in the spring of 1831, in European Russia and Poland, and in October invaded Hamburg, Berlin, and Vienna. In the same month cases were imported into Sunderland, and the disease remained epidemic in this country for fourteen months. Having thus reached the north-western angle of Europe, the epidemic divided into two branches, one of which crossed the Atlantic and appeared in Quebec in 1832, thence diffusing itself over the North-American continent; the other turned southwards, attacking successively France, Spain, Italy, and the Northern Coast of Africa. The disease did not finally leave Europe until the year 1837. Since the epidemic of 1817, numerous other epidemics have occurred in India, and several times the disease has slowly spread thence to Europe and to this country—not, however, always taking the same route as on the first occasion.

The first British epidemic was that, above referred to, of 1831–32, the second occurred in 1848–49, the third in 1853–54, and the last in 1865–66. On each of these occasions the disease was distinctly imported into this country by passengers or sailors coming direct from infected places, and its general prevalence was always preceded by local outbreaks in the seaport towns to which such infected visitors were admitted. The general history of these epidemics, so far at least as relates to England, has been

that isolated outbreaks occurred in the autumn of the first year, that the disease died out with the approach of winter, and reappeared with extreme virulence in the later spring, summer, or early autumn of the second year, lasting for some two or three months, and then disappearing altogether. It might seem from this that its prevalence was largely determined by season; and, indeed, there is strong evidence to show that on the whole high temperature is favourable, and cold inimical, to its spread. Yet, on the other hand, the disease has prevailed with the greatest severity in Moscow, Sweden, and other northern regions in the depth of winter.

To what cause or causes is epidemic cholera due? This is a question which has been the subject of innumerable discussions and investigations during the last fifty years. The horror which the disease occasions, the slowness yet certainty of its onward march, its sudden and capricious outbreaks, and its equally capricious subsidence and then total disappearance, all conspire to invest it with an atmosphere of mystery. Like influenza, it is the very type of an epidemic disease; and, therefore, like epidemic disease generally, has been largely held to be due to some atmospheric or telluric condition, some peculiar 'epidemic constitution' which, diffusing itself from country to country, gives to the prevailing maladies a choleraic character, and produces, where local circumstances are favourable, an outbreak of the fully developed disease. There is much to be said, no doubt, in favour of this view; but the questions then naturally arise—'On what does this epidemic constitution depend?' and 'What are the local conditions which favour its operation?' These questions are not easy to answer. We may point out, however, as bearing on them: that, although heat and climate have (as has been said) some influence over the propagation of the disease, there is no good reason to believe that moisture or drought, or excess or deficiency of electricity or ozone, affects it either one way or the other; that, according to Pettenkofer, localised outbreaks of cholera are determined in great measure by peculiarities of soil—the ground must be porous and a superficial layer of it unoccupied by 'ground water' and penetrable by air; that, as shown by numerous observations, the disease is much more apt to prevail in low-lying districts than in those which are much elevated above the sea; and that vegetable fungi, which have been detected by numerous observers in cholera-stools, have often been assumed to pervade the atmosphere and to be the specific cause of cholera. Lastly, in relation to the subject now under discussion, it may be pointed out that cholera has often been attributed to the accidental or designed poisoning of springs, and to the use of diseased cereals, especially rice, and even of unripe fruit.

Again, in favour of the dependence of cholera on some miasm or epidemic constitution was the striking fact that, although cholera affected large numbers of persons within a short time, there was little evidence of its communicability by direct contagion. It was noticed, and has been constantly observed, that nurses or medical attendants seldom, if ever, take the disease from patients under their charge, and that the introduc-

tion of cholera patients into a general hospital is by no means necessarily followed by the communication of the disease to other patients.

Nevertheless, it has always happened that the spread of cholera epidemics has followed lines of traffic, showing that human intercourse, not winds, has been instrumental in their propagation. In every invasion of this country, the disease has first been distinctly imported into our sea-port towns by the arrival thither of infected persons from infected localities; and has been thence carried by like means to other localities in direct relation with them by railways or other lines of traffic, and has thus gradually become distributed throughout the country, not generally, but by local outbreaks. The fact that cholera, though obviously not directly contagious, or at all events not directly contagious in a high degree, yet had some mysterious relation with the movements of mankind, and never broke out in any isolated country or town without having been distinctly imported into it by human agency, was manifestly opposed to most of the theories of its causation which have been previously referred to and had generally prevailed. Dr. Snow, now some years since, first shrewdly suspected that the cholera contagium was contained in the cholera evacuations, and that the disease was propagated by the entrance of minute quantities of such evacuations, for the most part through the medium of contaminated water, into the alimentary canal. And numerous subsequent investigations, some of the most remarkable being conducted by himself, have entirely confirmed the correctness of his provision. The matter is so important that we may quote some of the best established and most striking cases.

The cholera epidemic of 1849 was specially severe in the south of London, which was supplied with drinking-water mainly from surface wells and by two water companies—the Southwark and Vauxhall and the Lambeth—which derived their water from the Thames (the one in the neighbourhood of Hungerford Bridge, the other in that of Battersea Fields) and supplied it in a very imperfectly filtered condition. At that time all the sewers of London discharged themselves into the Thames, the water of which was consequently very foul. The cholera epidemic of 1854, also, was very severe in South London. But between 1849 and 1854 the Lambeth Company had removed its intake from Hungerford Bridge to Thames Ditton, and consequently furnished an infinitely purer water than it had done in 1849; the other company continued to draw its water from the neighbourhood of Battersea Fields. At this time the two companies were acting in rivalry, so that in many streets their mains ran side by side, and houses, under the same sanitary conditions in other respects, received a different water supply. A careful investigation of the distribution of cholera in South London in this year, conducted mainly by Dr. Snow but with the assistance of the Registrar-General, gave the following results:—

	Population in 1851	Cholera Deaths in 14 weeks	Cholera Deaths per 10,000.
Houses supplied by Southwark Co. .	266,516	4,093	153
„ „ „ Lambeth Co. .	173,748	461	26

The facts were even more remarkable when examined in detail, inasmuch as in streets and localities which both companies supplied the disease singled out the houses furnished by the Southwark Company.

During the same epidemic a remarkable outbreak occurred within a limited area, in the neighbourhood of Golden Square, London, the facts of which were also examined into by Dr. Snow. There had been a few cases in the neighbourhood during the month of August, including altogether up to the 30th nine deaths. On the 30th at least eight cases which ultimately proved fatal occurred; on the 31st, fifty-six; on September 1, one hundred and forty-three; on the 2nd, one hundred and sixteen; on the 3rd, fifty-four; and then daily until the 9th, forty-six, thirty-six, twenty, twenty-eight, twelve, eleven; after which the disease rapidly disappeared. No less than six hundred and sixteen persons were ascertained to have been attacked fatally with cholera within this area between August 19 and September 30, of whom at least four hundred and fifteen contracted the disease between August 31 and September 4 inclusive. It would take much more space than is at our disposal to enter fully into details; suffice it to say that Dr. Snow's investigations proved beyond the shadow of a doubt that this sudden and evanescent outbreak was distinctly due to the use of the sewage-contaminated water of the Broad Street pump, occupying the centre of the affected area, the water of which was held in great repute, and was largely drunk by those who lived in its neighbourhood.

Again, the epidemic of 1866 was remarkable in the fact that it was almost limited to a circumscribed area in the East of London, including Bethnal Green, Whitechapel, St. George's, Stepney, Mile End, and Poplar, together with the suburban districts of Stratford and West Ham. The inquiries of Mr. Radcliffe, conducted under the direction of the Medical Officer of the Privy Council, demonstrated with almost mathematical precision that the localisation of the epidemic was almost entirely due to the distribution to these districts of impure and unfiltered water by the East London Water Company.

It must be assumed, therefore, as a fact that the choleraic poison at all events, in a large number of cases, is conveyed through the medium of foul drinking water, and necessarily, therefore, by means of all articles of food or drink to which such water is added. But it still remains to ask — 'How does the poison reach the water, whence does it come, and what is it?' It would naturally be supposed that the choleraic poison is contained in the cholera stools; and indeed there is plenty of evidence to show that the drinking of water directly contaminated with small quantities of rice-water evacuations has induced cholera; and, as regards the local outbreaks above adverted to, it is certain that the incriminated waters were contaminated with sewage, and that there was at least the probability that the sewage contained the evacuations of cholera patients. But, on the other hand, there is good reason to believe that the freshly passed stools are not specifically noxious. Much, however, of what seems mysterious in reference to these matters appears to be explained

by the important experimental inquiries first conducted by Professor Thiersch, and since repeated by Dr. Sanderson in this country. The experiments which yielded the most striking results were those performed on mice. It was ascertained by these gentlemen that when, under certain conditions, mice were fed with cholera evacuations, they were attacked with symptoms which proved rapidly fatal, and that both symptoms and post-mortem appearances had a very close resemblance to those of human cholera. The chief points of likeness consisted in the rapidity and intensity of the disease; in a remarkable lowering of the temperature (sometimes as much as 20 degrees); in the accumulation in the intestines of thin fluid containing bacteria, other lowly organisms, and abundance of shed epithelia; and in the discharge of loose stools from the anus. The method adopted by Dr. Sanderson to infect the mice was to soak pieces of filter-paper in fresh cholera evacuations, or in the contents of the bowels of patients dead of cholera, to dry them, to ascertain by weighing the quantity of solid matter thus added to them, to cut them into pieces an inch square, to soak them in bacon fat, and then to administer them to the mice. The mice under these circumstances ate them greedily. The consequences were: that of mice fed with paper prepared from evacuations, which had not been allowed to stand more than twenty-four hours, or on the first day after passing, 11 per cent. were affected; that of those fed with paper prepared on the second day, 36 per cent.; that of those fed with paper prepared on the third day, every one; that of those fed with paper prepared on the fourth day, 71 per cent.; and that of those fed with paper prepared on the fifth day, 40 per cent. Paper prepared subsequently had no effect. These experiments show: that the cholera evacuations have little or no intensity of action when perfectly fresh; that their virulence increases up to the third day, diminishing during the fourth and fifth days; and that they lose all specific properties after that date.

The evacuations from the diseased mice produced the same effects on healthy mice as did true cholera evacuations; and, further, all experiments made by Dr. Sanderson in the month of November failed absolutely, probably, as he suggests, on account of the low temperature then prevailing.

The application of the above results in explanation of the phenomena connected with the causation of cholera is obvious. And it is fair to conclude from them, and from the other facts which have been adduced: that the specific poison of cholera is furnished by the discharges from the alimentary canal; that these are not operative when completely fresh, but acquire virulent infectious properties in the course of the following two, three, four, or five days, and subsequently lose them; that the poison of the disease is taken up by, or acts upon, the mucous membrane of the bowels, which it reaches through the mouth; and that, while undoubtedly it may be conveyed to the mouth under uncleanly circumstances from saturated bedclothes, and direct contamination of culinary utensils, food, or fingers, larger outbreaks of the disease are due to the infection of

drinking-water (well, pond, or river) with cholera poison derived from cesspools, sewers, or other such sources.

There can be little doubt, from the fact of its active powers of multiplication, that the cholera poison is an organised contagium; that one phase of its normal active existence is passed externally to the body; but that that phase is commonly of short duration, and probably readily arrested or rendered innocuous by cold and other agencies. It may here be mentioned that in the year 1884 Koch, who went out to India to investigate the etiology of cholera, discovered a specific bacillus or spirillum in the mucous membrane and contents of the bowels of patients dying of the disease, and also in a tank which supplied a district in which cholera was prevailing. This, from its curved form, he named the comma bacillus. The commas are about half as long as tubercle bacilli, display active movements, and not unfrequently are arranged in spiral threads having a close resemblance to the spirilla of relapsing fever. Though apparently found constantly associated with cholera, and capable of cultivation, they have not hitherto been proved to impart cholera, and hence it is, to say the least, very doubtful whether, as Koch maintains, they constitute the choleraic contagium.

*Symptoms and progress.*—The duration of the incubative stage of cholera is not known certainly. It probably varies generally between a few hours and three days. The symptoms of invasion present considerable variety. In some cases an indefinable feeling of malaise, associated with noises in the ears and lowness of spirits, precedes all other symptoms. In a large proportion of cases (either in succession to the above phenomena or arising independently) there is more or less looseness of bowels (premonitory diarrhoea) coming on a few hours, a day, or even two or three days, before the nature of the disease is distinctly revealed. Premonitory diarrhoea of even longer duration has not unfrequently been observed; but in most such cases there is reason to suspect that the relation of the diarrhoea to the subsequent attack of cholera was accidental only. Lastly, in some instances the invasion of cholera is sudden. Omitting the premonitory symptoms which have just been considered, the first indication of an ordinary attack of cholera usually consists in the sudden and uncontrollable evacuation (with or without pain) of an abundant loose stool, composed mainly of the proper contents of the alimentary canal in a fluid or semi-fluid state. To this succeeds a continuous or intermittent flux of fluid, at first bile-stained, but subsequently thin, colourless, or opaline, without faecal look or smell, and containing in suspension whitish flocculi. The amount of fluid thus discharged is sometimes enormous; four or five pints, or enough to fill a chamber-pot, may be passed in the course of an hour or two. Sickness for the most part attends the diarrhoea, but generally comes on a little later. The matters first vomited are the ordinary contents of the stomach and of the duodenum; but after these have been got rid of, the vomited fluid exactly resembles that which is flowing simultaneously from the anus, and may be almost as abundant. Shortly after vomiting and diarrhoea have become

established, severe cramps, attended with agonising pain, come on in the thighs and calves, in the arms, hands, feet, and parietes of the abdomen. And very speedily the patient falls into a state of extreme collapse—the so-called ‘cold’ or ‘algide’ stage; his tissues shrink; his fingers and toes get shrivelled and corrugated, and his eyes sink into their sockets; his surface becomes more or less notably livid, and sometimes as blue as that of a cyanotic patient—this change being specially noticeable in the hands, feet, cheeks, lips, around the eyes, and in the tongue, which looks like a piece of lead; his respirations are rapid and shallow, and his voice hoarse or squeaking, feeble, and reduced almost to a whisper; his pulse gets rapid and thready, and soon scarcely, if at all, perceptible at the wrist or even in the brachial artery. At the same time his temperature falls; his surface become cold and clammy, and sometimes covered with cold sweats; and his tongue and breath also get manifestly cold. The temperature in the mouth and axilla falls rapidly to  $95^{\circ}$ ,  $94^{\circ}$ , or even  $92^{\circ}$ ; and much lower temperatures than these have been recorded. But while the general temperature, and especially the surface temperature, thus falls, that in the rectum and adjoining parts may stand at  $101^{\circ}$ ,  $102^{\circ}$ , or even  $105^{\circ}$ . The urinary and biliary secretions are totally suppressed. The patient is wakeful and restless, throwing his arms about, probably complaining much of intense thirst and burning at the chest, but withal singularly apathetic. When the condition of collapse is fully established the vomiting and diarrhœa either cease completely or greatly diminish, and the patient lies ghastly and livid like a corpse, with eyes open and pupils dilated, torpid, yet still retaining his senses. During this period the muscular power is extremely enfeebled; yet occasionally the apparently moribund patient will rise up in his bed, and even get up and walk across the room. The duration of this stage varies from two or three to thirty hours or more, and then ends in death, secondary fever, or convalescence. Death, in collapse, sometimes occurs in the course of two or three hours; more frequently supervenes after the eighth hour—especially between the tenth and fourteenth; but is seldom delayed beyond the twenty-fourth.

The symptoms above described are not all developed in every case of cholera. The muscular cramps are sometimes altogether wanting; while in some cases, and these perhaps cases of no great severity, they are constant and agonising. Again, vomiting and diarrhœa are not invariably present; and indeed their absence is almost characteristic of some of the most formidable attacks of the disease—those, namely, in which the patient is suddenly struck down with symptoms of extreme collapse, and dies in the course of an hour or two, or less.

In those patients who survive the period of collapse a gradual change of symptoms supervenes. The stage of reaction sets in. This stage is said to be often wanting in the cholera of hot climates. In our own country, however, it is always present; but its duration and the severity of its symptoms depend very largely on the intensity and duration of the cold stage which preceded it. It generally comes on between the twelfth and the thirtieth hour after invasion. Its first indications are slight and

vague. A general improvement is visible in the patient; he becomes less restless, his breathing slower and more natural, his pulse just perceptible at the wrist; the lividity of surface slowly disappears; the shrunk tissues expand; the temperature rises; perspiration breaks out; and not improbably he falls into a comfortable sleep; urine begins to be secreted; and the motions are again stained with bile. The temperature, however, generally rises somewhat above the normal, and more or less obvious febrile disturbance takes place. In some cases the reactionary symptoms remain mild and end in convalescence in from twelve to twenty-four hours; but more commonly they undergo aggravation, and may then be prolonged (unless cut short by death) to between four and twelve days, sometimes longer. The general symptoms have some resemblance to those of enteric fever; the face becomes flushed, the eyes injected, the skin hot and sometimes studded with roseolous patches, the pulse increased in power and volume and accelerated, the respirations a little more rapid than natural, the tongue furred, sometimes dry and brown, and the temperature one, two, or three degrees above the normal; the patient may also present more or less delirium, or lie in a torpid or comatose condition. The motions, according to Dr. Sutton's observations, often consist on the first establishment of reaction of a thin, yellowish fluid, which looks like, and may be mistaken for urine, and often contains a kind of gelatinous substance; but soon they get green from contained bile, next peasoup-like, and then, consolidating, gradually acquire the normal character. Occasionally, early in the stage of reaction, the stools contain blood—the quantity varying from a mere trace, just sufficient to impart to them a pale pink tinge, up to a flux sufficient to undergo very complete coagulation. The stools of the reactive period are often very fetid. The re-establishment of the urinary secretion is a most important element in the progress of the disease. In mild cases it sometimes takes place in twelve hours or less; but it is more common on the second or third day, and may be delayed until the fourth, fifth, or sixth day. The urine first passed is in extremely small quantity, and often, during the first twenty-four hours, remains far below the healthy average. Subsequently the patient may pass four, five, or six pints daily. At first it is a little turbid, contains traces of albumen, casts of the urinary tubules, and epithelial cells from other parts of the urinary passages, but presents a very small amount of urea and uric acid, as also of chlorides, phosphates, and sulphates. The colour varies. Subsequently, while during the progress of fever the urine becomes more copious, the amount of urea in it increases, and may even exceed the healthy standard. Urocyanogen is sometimes found in the urine.

The causes of death in the stage of reaction, and the phenomena which precede it, present considerable variety. Sometimes cough and difficulty of breathing, with pulmonary engorgement or consolidation, carry the patient off. At other times he seems to sink under the continuance of intestinal flux, especially when hemorrhage accompanies it; or symptoms much like those of enteritis supervene. In some cases con-

vulsions, coma, or other cerebral symptoms, which there is good reason to believe are not unfrequently due immediately to uræmic poisoning, precede and apparently cause death. Lastly, the patient sometimes sinks from mere asthenia, arising directly out of his primary symptoms, or supervening on his typhoid condition.

In the description of cholera above given we have adverted to some of the varieties which its attacks present. Especially we have pointed out, or incidentally mentioned: that in some cases the patient is struck down by the disease, and dies in extreme collapse at the end of perhaps two or three hours, without ever having passed an evacuation; that in a still larger number of cases the characteristic vomiting and diarrhœa are present, the stage of collapse gradually supervenes, and the patient dies in this stage at the end of from (say) ten or twenty-four hours; that in many cases again, even of considerable severity, the patient emerges from the condition of collapse into one of febrile reaction, during which he may perish in one of the modes above enumerated, or from which he may glide into convalescence; and, lastly, that in some cases, notwithstanding the presence of rice-water stools and other quite characteristic signs of the disease, the patient scarcely becomes collapsed at all, and very speedily regains health and strength. This enumeration leads up to the important questions, as to how far cholera may be so mild as to simulate in its attacks mere summer or autumnal diarrhœa, and how far also it is possible that the latter which (in this country, at all events) concurs with the epidemic prevalence of cholera is influenced by the choleraic poison. As to the former question, there can be no doubt, we think, that, just as enteric fever, typhus, scarlatina, and other like affections are sometimes so mild and slightly developed as to be (except it may be from associated circumstances) incapable of identification, so cholera may be so mild and so shorn of everything characteristic as to be unrecognisable as cholera; and hence that cases of undoubted cholera may simulate, and be taken for, cases of ordinary unspecific diarrhœa. As to the latter question, it may be remarked that those who regard cholera as being the outcome of some 'epidemic constitution' of the atmosphere, or of some all-pervading miasm, might reasonably believe that all morbid conditions tend during the prevalence of cholera to take on a choleraic character. Those, however, who believe the choleraic poison to be a form of contagion, and accept those views of its operation which we have endeavoured to uphold, would necessarily discredit its general influence, excepting in the face of overwhelming evidence in favour of the existence of such influence. But no such evidence, we think, exists. It seems to us, indeed, a fundamental and mischievous error to regard the diarrhœa which precedes and accompanies epidemics of cholera as having any other than a fortuitous connection with them.

The mortality of cholera is very great; it varies in different countries and in different epidemics, but in round numbers may be estimated on the average at about 50 per cent. It is said to be less fatal towards the close of an epidemic than at its commencement; and, further, to be more

fatal to the very young and very old than to those whose age lies between these extremes.

Any affections attended with sudden and extreme collapse, especially if there be at the same time gastro-intestinal disturbance, may be mistaken for cholera. Among those most liable to be thus confounded are arsenical poisoning, and poisoning by croton-oil; severe summer cholera; perforation of the stomach or bowel; extensive enteritis; and the onset or cold stage of severe remittent fever.

*Morbid anatomy and pathology.*—The appearances found after death from cholera differ according as death takes place in the stage of collapse or in that of reaction. In the former case, the body retains much of the shrivelled character and lividity which it presented during life, and the dependent parts are often deeply congested. The muscles not unfrequently contract for some little time after death, causing movements of the limbs; and for the most part rigor mortis is well marked and prolonged. The tissues of the body are preternaturally dry, the muscles firm and dark-coloured, and the systemic veins loaded with blood which is manifestly thicker and perhaps darker than normal. For the most part the serous cavities are empty of fluid and their surfaces sticky to the feel, and they not unfrequently present subserous petechial extravasations. The right cavities of the heart are always full of dark-coloured, imperfectly coagulated blood. The left ventricle is sometimes firmly contracted and empty, sometimes contains a little fluid blood or clot. The left auricle also presents a small quantity of blood. The lungs are usually much diminished in weight, pale, anæmic, and dryish on section. Sometimes, however, they are congested and œdematous below, and they may even be congested and œdematous throughout. The pulmonary arteries are usually gorged with blood, the veins nearly or quite empty. The liver presents no decided departure from health, and the gall-bladder is full of bile. The spleen generally is reduced in size. The outer surface of the bowels is often injected or of a diffused rosy tint. Their mucous membrane is sometimes of a nearly uniform pink tinge, increasing in intensity towards the cæcum; or it may present irregular patches of congestion, with submucous extravasations; or it may be quite pale. It often exhibits a corrugated and sodden appearance; and the solitary and Peyer's glands are for the most part enlarged. The contents are an opaline or gruel-like fluid, which is sometimes white, sometimes pink from admixture with blood. The mucous lining of the stomach is often congested and mammillated, and the contents generally resemble those of the bowels. The kidneys are congested on the venous side, so that the medullary portions and the superficial veins are injected, while the cortical substance remains more or less pale. The urinary bladder is firmly contracted, and empty or containing a little pus-like fluid. The brain presents numerous *puncta cruenta*.

If death occurs during reaction, the tissues are found moist; blood occupies, perhaps in equal degree, both sides of the heart, and not unfrequently thick fibrinous coagula are prolonged thence into the aorta; the lungs are congested and œdematous; and the contents of the intestines

present the appearance of pea-soup. Besides which changes pneumonia is sometimes met with, sometimes distinct inflammation of the intestinal mucous membrane.

Other pathological facts of great interest have been ascertained with respect to this disease. Although, as has been stated, the blood is inspissated, it is not by any means so much so as is commonly believed; but (according to Dr. Thudichum) it is more adherent to the blood-vessels than natural. The proportion of albumen and salts to its other solid constituents is diminished; and the white corpuscles are often increased relatively to the red. The rice-water fluid, as found in the intestines, is alkaline, in a state of rapid decomposition, evolves gases (chiefly nitrogen and carbonic acid), and contains, besides bacteria, shed epithelium in abundance, mucine, albumen, and also butyric acid, acetic acid, ammonia, leucine, and inorganic salts. It does not, however, contain urea. There is no doubt that after death the mucous surface of the bowels is found to have lost its epithelial covering, which is thrown off in flakes and suspended in the intestinal contents. But it is uncertain whether this is merely a post-mortem change or a lesion occurring during life. It is probably the latter, however, for there appears to be a similar tendency to shed the epithelium in almost every other part in which epithelium exists, especially in the bladder and urinary passages, in the bronchial tubes, and in the ducts of the liver and salivary glands. Dr. Thudichum's observations show that during the period of collapse the blood and the tissues contain very little urea, but that its quantity increases during the period of reaction, and soon, if urine be not secreted, becomes excessive.

It remains briefly to discuss the relations between the post-mortem appearances and the vital phenomena of the disease. It is obvious that we here have an affection which is characterised primarily and mainly by a sudden and profound impression on the mucous surface of the alimentary canal; in dependence on which, active destructive changes take place (as evidenced by the raised temperature of the parts) and large quantities of imperfectly filtered blood, with tendency to rapid decomposition, are poured forth with sudden impetuosity. This rapid and profuse discharge tends to cause inspissation of the circulating blood, and consequently indirectly, but very thoroughly, to drain the tissues of their interstitial fluid, and to cause them to shrivel up. Anasarca, indeed, if present, becomes thus temporarily cured. The absorption of extra-vascular fluid into the blood-vessels tends, of course, to maintain the fluidity of the blood; but, notwithstanding this, the blood almost invariably becomes thicker than natural, and less easy of transmission through the minuter vessels. On these conditions follow: contraction of all the smaller arteries, excepting, probably, those connected with the bowels; general failure of the circulation; arrest of normal destructive changes, and therefore of formation of urea; arrest of urinary, biliary, and salivary secretions; and diminution of the normal action of the lungs, with cyanosis, lowering of temperature, and general collapse. All the above phenomena flow directly or indirectly from the effects of the cholera

poison. But how and where does the poison act? Some believe that it acts simply on the intestinal mucous membrane as a violent local irritant, just as croton-oil or elaterium acts, and that all the symptoms which ensue are the result of this irritation of the mucous membrane and of the discharge which takes place from it; and there is no doubt that symptoms almost identical with those of cholera may be produced by the local action of irritants and irritant purgatives. But if it be true, as it seems to be, that the fœtuses of mothers dying of cholera themselves give clear indications of being affected with the disease, it is clear that the poison must be diffused throughout the system in addition to being contained in the alimentary canal. And, indeed, it is most consonant with all we know of similar diseases to regard cholera as a systemic affection. But whether we are therefore to assume, with Dr. George Johnson, that the choleraic virus is contained in the blood; that by its presence there it causes cramp of the voluntary muscles on the one hand, and of the capillary arteries of the lungs on the other, so as to prevent the passage of blood through them; that the general collapse, loss of temperature, and suppression of secretions are due to this mechanical obstruction; and, lastly, that the discharge from the bowels is an effort of nature (which should be encouraged) to eliminate the poison from the blood, is quite another matter. We confess that, in our view, the intestinal flux is not eliminative, but connected, as is the eruption of small-pox, with the local growth and multiplication of the poison; and that there is ample explanation in the processes going on in the bowels of nearly all the subsequent phenomena of the disease, including collapse. It is obvious, however, that the presence of inspissated blood in the vessels, the drying up of the moisture of the tissues, the contraction of the smaller branches of the pulmonary artery (assuming it to take place), must all co-operate to maintain the patient in the condition of collapse.

*Treatment.*—The value of precautionary and hygienic measures in preventing or limiting the outbreak of cholera has never been better shown than in the history of our own epidemics. Pure water, well filtered, and carefully guarded from fœcal contamination; thorough domestic cleanliness; and, when cholera is present, the immediate disinfection by carbolic acid or Condy's fluid of all evacuations and contaminated articles, are conditions of the utmost importance in preventing the spread of the disease.

The medicinal treatment of cholera resolves itself into that of the prodromal stage, that of the period of collapse, and that of the stage of reaction. It is commonly believed that the treatment of the premonitory diarrhœa is a matter of vital importance to the patient; and the assumption that the diarrhœa, which so often prevails when cholera is epidemic, is actually cholera, or simple diarrhœa modified by choleraic influence, has led to a general belief in the importance of treating at such times all diarrhœal cases with the object of preventing their development into the graver malady. But unfortunately, while the majority of physicians laud astringents for this purpose, others prefer castor-oil, and all refer to

statistics in proof of the efficacy of their respective modes of treatment. We have asserted our own belief that, if a case be one of simple diarrhœa, it will not run on to cholera under any form of treatment ; and we may add that, if the case be one of commencing cholera, there is no more ground for believing it can be cut short than for believing that typhoid fever or whooping-cough can be cut short. We do not believe that either castor-oil or astringents have any such influence.

In the period of collapse all sorts of remedies have been adopted ; some have given calomel in large doses, some opium, some brandy, some castor-oil ; but it seems clear that drugs administered by the mouth must in such cases be inoperative. And this is certainly the opinion of nearly all except the enthusiastic supporters of some special drug. During this stage the patient should be kept in the horizontal position ; he should be allowed cold or ice-cold water to relieve his insatiable drought ; and his surface should be kept warm by the application of hot bottles or flannels, or by friction. The placing of the patient in a bath, two or three degrees above blood heat, is often very comforting and apparently of much service. The vapour bath is equally beneficial. It is in this stage that the injection of saline fluids into the veins has been so frequently tried, and occasionally with success. The immediate effect of the injection is often marvellous, the moribund patient regains his healthy appearance, his respirations, pulse, and voice resume their normal characters, and he sits up in bed conversing cheerfully. But the improvement is generally of short duration ; he falls again into collapse, and probably dies. The solution employed should resemble as nearly as possible the serum of the blood, and should be injected slowly and cautiously, in quantities varying, according to its effect, between 10 oz. and one or two pints. Schmidt recommends the following :—Chloride of sodium 60 parts, chloride of potassium 6, phosphate of soda 3, carbonate of soda 20 ; of which mixture 140 grains are to be dissolved in 40 oz. of distilled water and filtered. The temperature of the fluid as it enters the veins should be a little over that of the blood. Cramps may be relieved by friction, or the inhalation of chloroform.

Great care must be taken of the patient during the reactionary stage. He should be kept cool. Diarrhœa and vomiting must be restrained : the former by astringents, such as Dover's powder, compound kino powder, or the aromatic powder of chalk and opium ; the latter by lime-water, bismuth, and the like, or the use of ice or the application of counter-irritants. The food should be fluid, nutritious, and unstimulating ; milk, broth, arrowroot, sago, barley-water, and eggs are the most appropriate. It is questionable whether stimulants are beneficial. If resorted to they should be given in small doses much diluted. It is of essential importance that the urinary secretion be restored, but it is unwise to employ stimulant diuretics for the purpose. Saline effervescent may relieve sickness and at the same time promote urine. Cupping-glasses and counter-irritation to the lumbar region are believed to be serviceable. If dysenteric or enteritic symptoms come on, opium must be freely used.

XX. HYDROPHOBIA (*Rabies*)

*Definition.*—A disease special to dogs, wolves, foxes, and animals closely related to them, among which it spreads by direct contagion, and from which it is imparted (but by inoculation only) to other animals and to human beings. Its most characteristic features in man are the spasms and terror which are induced by the attempt to swallow fluids, or even by the thought of swallowing, and its invariably and rapidly fatal issue.

*Causation and history.*—There is no evidence to show that this disease ever arises spontaneously among dogs any more than small-pox does among men; and, further, there is reason to believe that it spreads among them by inoculation only, or rather, perhaps, by the introduction of the saliva of diseased animals into the tissues of those which are healthy, by whatever process that introduction is effected. The cause of the disease is evidently a specific virus which resides mainly in the viscid secretions furnished by the mucous membrane of the mouth and fauces and by the salivary glands. The prevalence of rabies, like that of other infectious diseases, varies very greatly at different periods; sometimes it is scarcely seen for many years together, at other times it prevails widely in an epidemic form. The circumstances on which these differences depend are obscure; for climate, season, dearth of water and of food, and other such conditions, do not seem to have any influence over it. It is important, however, to know that the virus never inoculates when it is applied to the surface of the sound skin; and that only a small proportion of those who are bitten by rabid dogs become hydrophobic. This proportion has been variously estimated at from 5 to 50 per cent. One main reason doubtless of the immunity, which so many who are bitten enjoy, is the fact that they are wounded through their clothes, and that the fangs are thus cleansed from all moisture before they enter the skin.

*Symptoms and progress.*—After a man has been inoculated with the saliva of an animal suffering from rabies, the wound in most cases heals as readily and quickly as a wound not so inoculated would heal; at all events, there is nothing in its progress to indicate the existence of anything unusual. A period of latency follows, which is generally remarkable for its long duration. In most cases the first symptoms show themselves between the fourth and eighth week, but they have appeared in the course of a few days, and have been delayed for months, and even, it is asserted, for several years. They rarely, however, appear after four months. The outbreak of hydrophobia is in some cases preceded for a day or two by heat, tingling, or pain at the part on which the injury was inflicted, the pain sometimes being intense and extending upwards in the course of the sensory nerves. There is occasionally also renewed inflammation and suppuration or ulceration. In many cases, on the other hand, no such phenomena present themselves.

The period of invasion, which is sometimes termed the *melancholic stage*, is attended with a variety of symptoms, most of which have no particular significance, and which gradually merge in those of the fully developed disease. The patient complains of feverishness and shivering, with dryness of mouth and thirst, want of sleep, epigastric uneasiness, and indefinable anxiety. He is pale, anxious, but distraught in his aspect, with restless eyes and dilated pupils, restless and fidgety in his movements, garrulous, but speaking in short sentences and in a jerky abrupt manner. He suffers also from increased frequency of the heart's action and loss of appetite, perhaps nausea and vomiting; and not improbably has even now some feeling of constriction about the fauces with a disinclination to swallow fluids, quickened and sighing respiration, general hyperæsthesia, and a tendency to priapism and seminal discharges.

At the end of two or three days the next stage has become fully developed. This is sometimes termed the *stage of excitement*, and in it the disease assumes all its typical features. The strange agitation of the patient has become more marked; his eyes are bright, mobile, wild, and glance with suspicion or terror about him; his hair is rough, his skin pale, his brow contracted, his aspect indeed closely resembles that of a patient with acute mania; he is still inclined to be talkative, frequently making odd but pertinent remarks; he is probably quite sensible, and capable of understanding and reasoning; at the same time he is obviously under the domination of some indefinable but great horror; and occasionally perhaps he has hallucinations, and is liable to outbreaks of violent maniacal excitement in which he may endeavour to injure himself or others. The thirst has increased; his mouth and fauces are congested and dry; and a quantity of tenacious saliva accumulates, which he is constantly hawking up and spitting about him with a noise which has often been taken for a bark. But, above all, the disinclination to swallow fluids has now become an almost perfect inability to swallow them, and a dread of making the attempt. He will still perhaps resolutely try to drink, will take the glass of water in his hand, prepare himself with strange calm and deliberation to make one supreme effort, put the vessel hurriedly to his lips, make a sudden gulp, and then, with or without swallowing a little of it, eject the bulk of it spasmodically and violently from his mouth and throw the glass away. A convulsive attack has been induced, marked by general tremors or shuddering, and violent spasmodic action of the muscles of deglutition and respiration, which lasts for a few seconds, and leaves the patient for a minute or two in a state of painful agitation. The fear of the recurrence of these terrible convulsions is constantly before him, and their actual recurrence is soon induced, not merely by the attempt to swallow, but even by the sight or sound or thought of fluid. The general hyperæsthesia, which has already been adverted to, becomes more acute. The patient will often complain of the mere weight of the hand, or of his bed-clothes; and a draught of cold air on the surface suffices to induce a convulsive attack. Bright objects, and loud, harsh, or unaccustomed sounds are painful to him, excite a feeling of terror, and not unfrequently also pro-

voke convulsions. The sexual excitement, of which the patient complains bitterly, may also continue. He passes urine frequently.

As the disease progresses all the symptoms become more severe ; the patient gets feebler, his pulse quick, irregular, and small, his skin clammy, his voice hoarse ; the tenacious mucus which is secreted by the mouth and fauces accumulates and becomes more difficult of expulsion ; the paroxysms of general convulsive action and of spasm of the respiratory muscles increase in severity and frequency ; and at length he dies either of sudden asphyxia in one of these convulsive attacks, or of slow asphyxia induced by their rapid recurrence, or of exhaustion, aided possibly by a general paralytic condition.

The most remarkable phenomena of the disease are : first, the hyperæsthesia of the skin and organs of sense ; second, the tendency which impressions on these organs, and attempts to swallow or thoughts of swallowing liquids, have in producing clonic and tonic spasms of the respiratory muscles ; and, third, the wakefulness, horror, and tendency to yield (while apparently still quite rational) to insane impulses. The last condition is occasionally absent ; or the patient only rambles slightly immediately before death. The disease is invariably fatal, and generally terminates between the second and fourth day.

Rabies in dogs presents in great measure the same symptoms as hydrophobia in man. There are, however, one or two important points of distinction : namely, dogs are not afraid of water, and will indeed bury their muzzles in water while at the height of the disease ; cutaneous hyperæsthesia seems to be absent in them : and towards the close a paralytic condition supervenes, involving especially the hinder extremities and the lower jaw.

A very important case, showing that hydrophobia in the human being may resemble in its symptoms the disease produced experimentally in rabbits, and often occurring in dogs, was admitted into St. Thomas's Hospital under our care in October 1886. The patient was a man thirty-six years of age, who had been bitten in many places by a rabid cat, and had subsequently been inoculated with the virus of hydrophobia according to M. Pasteur's method, and under his eye. Six weeks after having been bitten by the cat, and two or three after having undergone M. Pasteur's treatment, he was attacked with weakness in the upper and lower extremities and difficulty in swallowing. The symptoms increased upon him, and on the fifth day, having then been unable to swallow for two days, he was received into the hospital. At that time there was absolute motor paralysis in the lower extremities, with flabbiness of muscles and absence of tendon reflexes, but still some survival of superficial reflexes ; the upper arms also were absolutely motionless, but feeble movements could still be executed with the forearms and hands ; there was complete paralysis of the muscles of deglutition, so that his saliva and any fluids placed in his mouth accumulated at the back of his throat, and rendered breathing and speech difficult. There was no sensory paralysis or exaltation, no tenderness of muscles, no loss of power over the emunctories ; he was

quite sensible, had no delusions or other signs of mental aberration, and (though unable to drink) showed no dread of water. He had no convulsions. His pulse was under 100°, his respirations were about 15, and irregular, his urine was free from albumen, his temperature varied from 101° to 102·6°. In the course of the evening the paralysis of the arms became complete, and he passed into a state of coma, in which he died early the following morning. At the post-mortem examination nothing of any importance was discovered excepting some congestion of the dorsal region of the cord. The case would certainly have been chronicled as one of Landry's ascending spinal paralysis but for its remarkable history. The similarity between the patient's symptoms and those of rabies in dogs and rabbits was, however, recognised; and that the case was really one of hydrophobia was subsequently proved by the fact that the inoculation of rabbits by Mr. V. Horsley with portions of the spinal cord gave them true rabies.

*Morbid anatomy* has not yet thrown any important light upon the phenomena of hydrophobia. The muscles retain their rigidity for some time after death, and there is congestion of the posterior surface of the corpse, and of the fauces, pharynx, œsophagus, larynx, trachea, and lungs. Investigations<sup>1</sup> by Drs. Coats, Gowers, Greenfield, and others have demonstrated the presence of hyperæmia of the central nervous organs, with accumulation of leucocytes around the smaller vessels and capillaries of the cerebral convolutions, the ganglia at the base of the brain, the grey matter of the cord and especially that of the medulla oblongata. Small extravasations of blood have also been found in the grey matter of the dorsal and cervical regions of the cord. Dr. Coats further describes extravasation of leucocytes into the salivary glands, mucous glands of the larynx and kidneys. There can be little doubt that the hydrophobic virus exerts its influence mainly on the sensory and emotional regions of the central nervous organs. Marochetti, in 1820, described the formation of small vesicles beneath the tongue in persons bitten by mad dogs. These vesicles, which have also been described subsequently by one or two other physicians, are said only to occur during the second week after inoculation.

*Treatment.*—Whenever a patient has been bitten by a rabid animal, or one suspected of having rabies, the wounded part should at once be excised and the remaining raw surface freely treated with caustic potash, nitric acid, the acid nitrate of mercury, the actual cautery, or some equally efficient destructive agent. No remedy has been discovered competent to arrest the progress of the once established disease. Drugs producing narcotism and anæsthesia might seem to offer some chance of benefit, but it is doubtful if any has been found of service, except perhaps in the relief of suffering. It should be observed, however, that a case of recovery is said to have occurred in 1874, in the practice of Offenbourg, of Winkrath, under the use of injections of curara, of which about a third of a grain was administered every fifteen minutes or so. The patient was

<sup>1</sup> *Lancet*, vol. ii. 1877, p. 882.

well on the eighth day. Any drug that may be employed should be administered by inhalation, by the rectum, or by subcutaneous injection. Tracheotomy has been suggested in the hope of averting death by asphyxia. Great care should be taken to prevent the patient from doing violence either to himself or to those about him, and especially to prevent inoculation of wounds by the saliva which he disperses.

*Postscript.*—There is little, if any, reason to believe that true hydrophobia has ever been cured when once it has declared itself. But it is now scarcely open to doubt that Pasteur has discovered a method of inoculating with attenuated or modified virus, by which not only unprotected animals may be rendered insusceptible of hydrophobia, but such as are already in the incubative stage may have the progress of the malady permanently arrested. We propose, not to give a systematic account of his investigations, which have extended over a period of some years, but to furnish a brief statement of the chief conclusions at which he has arrived, and of the grounds which seem to justify them.

1st.—The virus of hydrophobia is present mainly in the saliva and salivary glands and throughout the whole of the nervous system (including the nerves) of rabid animals. It is especially abundant in the medulla oblongata and cord. This fact, apart from its practical importance, is interesting as confirming the belief that the contagia of infectious fevers tend to accumulate in particular organs or regions.

2nd.—Hydrophobia may be readily imparted by inoculation; but the consequences of its transmission from animal to animal are different for different species of animals. By inoculation from monkey to monkey the virus becomes weaker and weaker until it is no longer capable of giving the disease to dogs. On the other hand, by transmission through rabbits or guinea-pigs the intensity of the virus increases while the incubative period shortens, until at length the virus attains its maximum potency, and the incubation is reduced to seven or eight days. Further, virus reduced by passing through monkeys may have its virulence restored by transmission through rabbits or guinea-pigs. It is the rule with regard to cultivated hydrophobia that the shorter the incubation becomes the more virulent becomes the virus, and conversely.

3rd.—For the purposes of inoculation either saliva or salivary gland-tissue, or portions of the nervous centres, may be employed, and the virus may either be inserted under the skin, injected into a vein, or applied directly to the surface of the brain. The most certain results are obtained by employing infected cord or medulla, and injecting solutions of it either into a vein, or (after trephining) beneath the visceral arachnoid.

4th.—The symptoms of rabies show much variety even in the same species. This depends on the different degrees in which different parts of the nervous system happen to be implicated, and on the amount of poison introduced into the system. Dumb madness is the result of large involvement of the nervous centres, and generally follows from the injection of virus into a vein. Furious madness implies comparatively small presence of poison, and commonly results from the direct inoculation of the brain.

5th.—Virus aggravated by transmission through the rabbit, when kept in a dry atmosphere undergoes gradual attenuation, until at the end of some days its virulence is so far reduced that inoculation with it, though still followed by a definite effect upon the system, fails to cause the usual symptoms of hydrophobia or death. Inoculation with virus thus attenuated to harmlessness, but not yet to inertness, does not prevent, though it may delay, the effects of potent hydrophobic poison, already working in the organism. Such virus has, however, a preventive influence against the effect of a virus a little less reduced than itself. Disease imparted by virus attenuated by the above process retains its acquired shortness of incubation; and for this reason Pasteur thinks that the seeming attenuation is not due to any actual loss of potency in the micro-organisms, but to the formation by them of some substance which tends to neutralise their poisonous properties and to oppose their own development.

6th.—Assuming the above statements to be true, it would seem not difficult to deduce some method by which animals might be rendered invulnerable to hydrophobia, and even such as have been successfully inoculated might have the impending malady prevented. For, beginning with a safe virus, and then inoculating at short but sufficient intervals with virus of increasing potency, until finally virulent virus is used, it would seem likely that the first inoculation being protective against the second, the second against the third, and so on throughout the series, the later potent inoculations would be rendered innocuous, and protection for the future established. Also, considering that the normal incubative period of hydrophobia in dogs and men extends over several weeks, while that derived from the rabbit is only of seven or eight days' duration, it would seem likely (judging from the analogy afforded by the influence of cow-pox over small-pox) that the whole series of protective operations might be accomplished within the period of natural incubation, and forestall by their effects the effects of hydrophobia already contracted.

7th.—It is, in fact, on these principles that Pasteur's process of treatment is founded. It is as follows:—Every day he suspends in a jar (the air in which is dried by placing in it fragments of caustic potash) small pieces of the spinal cord of a rabbit just dead of virulent hydrophobia. The virus attenuates rapidly, so that at the end of ten days it is no longer capable of doing harm. The first injection is made with a portion of cord which has been dried for ten days. The second is made next day with a portion of cord which has been dried for nine days. The third is made on the third day with cord which has been kept eight days. And so on, until on the tenth day (which is the last) the injection is made with fresh cord—cord which would infallibly give virulent hydrophobia to any unprotected animal. For the purposes of inoculation the portions of rabid cord are mixed with sterilised broth, and a Pravaz's syringe (about a cubic centimètre) is injected under the skin of an adult patient. For a child a somewhat smaller quantity is employed. It is needless to add that all anti-septic and other precautions are taken.

8th.—By the above method it seems certain that Pasteur has succeeded

in rendering many of the lower animals insusceptible of hydrophobia, and there can, we think, be little doubt that he has also prevented the development of hydrophobia in many animals experimentally inoculated beforehand with potent virus, and in many human beings bitten by rabid animals and brought to him for treatment from all parts of Europe. It is well known that only a minority of persons bitten by mad dogs contract hydrophobia; and as it is impossible to tell beforehand whether a person thus inoculated will suffer or not, it was not unnatural to suspect in the beginning that much of Pasteur's apparent success was due either to the fact that his patients would have failed to become hydrophobic even if he had not treated them, or to the fact that they had not been bitten by rabid animals. But, on the other hand, the exceedingly small percentage of deaths from hydrophobia occurring among his patients, and the fact that all of them in the course of treatment have been harmlessly inoculated with virus capable of giving rabies without fail to dogs, seem to bear unanswerable testimony to the importance of his discoveries and the protective efficacy of his treatment.

## XXI. GLANDERS. FARCY (*Equinia*)

*Definition.*—A specific disease, special to the horse, and animals of the same genus, but communicable to man, and characterised by a peculiar tubercular affection of the nasal and respiratory mucous membranes, and of the skin, lungs, lymphatic glands, and other parts of the body.

*Causation and history.*—Whether or not the disease originates spontaneously in the horse is a matter of dispute. It is certain, however, that it spreads readily among horses, and from them to man by contagion—mainly by the virus contained in the secretions of the nasal mucous membrane; and, further, that it is similarly transmissible from man to man. Bacilli in the form of rods, about equal in length to tubercle bacilli, and believed to be specific, have been found in the seat of disease, and in internal organs.

*Symptoms and progress.*—The period of incubation probably varies generally between one and fifteen days; but it is said to be occasionally much prolonged. Two varieties of equinia are met with, which go by the respective names of *glanders* and *farcy*: the difference between them depending mainly on the seat of inoculation, and in the absence or presence of early affection of the nose and air-passages. These varieties run into one another even in the horse; in man they are generally combined. The symptoms of invasion are those of intense febrile disturbance—heat of skin, rigors, acceleration of pulse, headache, febrile urine, pains in muscles and joints, and often nausea and vomiting, and profuse perspirations. The specific phenomena of the disease soon follow. These consist in an affection of the nasal mucous membrane and of the mucous surfaces which are continuous with it, and an eruption on the skin.

The mucous surface of the nostrils becomes congested, and secretes a thin, acrid, watery fluid, which soon gets thick, tenacious and profuse, and probably assumes at length the character of sanious pus. The cutaneous eruption is thinly and irregularly scattered, and chiefly on the face, extremities, neck and abdomen. It consists at first of red points; but these soon increase in size, ultimately perhaps attaining the bulk of peas, and feeling hard and shotty between the fingers, and not unlike syphilitic chancres. A vesicle or pustule soon makes its appearance on the summit of each spot, enlarges, bursts, exudes a more or less abundant purulent fluid, and leaves an irregular sloughy ulcer, with a livid margin. A little later, other phenomena manifest themselves: the conjunctivæ yield a purulent secretion; sores arise on various parts of the mucous surface of the oral cavity and pharynx; bronchitic, pulmonic, or pleuritic symptoms are added; erysipelatous redness and swelling of the eyelids, nose, cheeks, and forehead become developed; and subcutaneous or deeper-seated tubercles and abscesses (the latter often of considerable size) appear in various parts, but mainly in the face and in the vicinity of joints. Whilst these symptoms are in progress, the patient becomes weak and prostrate, his pulse quick and feeble, his muscles tremulous, his tongue dry and brown, and delirium comes on; in a word, typhoid symptoms rapidly develop themselves, on which coma supervenes, and death soon follows. During this period the breath is fœtid, perspiration is profuse, there is often diarrhœa, and gangrene sometimes attacks the nose, eyelids, and other parts. The course of the disease is generally acute; the temperature may rise to  $104^{\circ}$  or even to  $106^{\circ}$ ; and death occurs, sometimes during the first few days, but more commonly between the seventh and fifteenth or sixteenth. Occasionally in man (but much more commonly in the horse) the disease is chronic. The invasion is then more gradual, the various phenomena follow one another at longer intervals, and the eruption is often absent; but the subcutaneous abscesses which form become larger, the resulting ulcers are often attended with sloughing, and the affection of the nostrils extends and leads even to the exposure and destruction of the bones. The patient passes into a hectic condition, and lingers for weeks, months, or years. The blood is said by Colin to be greatly surcharged with white corpuscles.

*Farcy* is generally dependent on the inoculation of a wound of the trunk or limbs. The inoculated part gets inflamed and painful, and the absorbent vessels and glands in relation with it soon become similarly affected. Then supervene more or less of the febrile disturbance that characterises glanders, and the formation of subcutaneous lumps (*farcy-buds*) and abscesses; often, too, the absorbent glands become generally inflamed, and suppurate. The cutaneous rash is not so frequently present in farcy as in glanders, and the nasal inflammation is often absent. Occasionally, however, all the special symptoms of glanders supervene. This variety of equinia may be either acute or chronic. In the latter case it is sometimes exceedingly ill-marked and difficult of diagnosis.

Equinia is generally a fatal disease. The chronic forms are most likely to be followed by recovery, and farcy more so than glanders. In its early stage, and in the absence of rash or nasal implication, equinia may be readily mistaken for acute rheumatism or pyæmia.

*Morbid anatomy.*—The anatomical phenomena of equinia consist mainly in the formation of tubercles, presenting to a great extent the structural features of true tubercles, and like these tending rapidly to undergo caseous degeneration and liquefaction or suppuration. When superficial, they speedily form unhealthy-looking ulcers. When deeper seated they become converted into abscesses, which then gradually enlarge and ultimately burst. The tubercles vary from the size perhaps of a pin's head to that of a pea or bean. It is to their development in connection with the mucous membrane of the nose that the peculiar symptoms referrible to this organ are due. They also form in the mouth and fauces, in the larynx, trachea, and bronchial tubes; and they appear in the substance of the lungs, producing a condition not unlike that of ordinary lobular pneumonia, and often inducing pleural inflammation. The cutaneous eruption is due to the growth of these tubercles in the skin; and the subcutaneous lumps and abscesses, and those which arise in the substance of muscles, are of the same nature. The kidneys, spleen, testicles, and other organs are also occasionally affected. Implication of the lymphatic glands is not unfrequent, but must be regarded as generally, if not always, secondary to specific lesions occurring in parts with which they are connected. More or less of simple inflammation is generally associated with the specific lesions.

*Treatment.*—It is impossible to lay down any authoritative rule for the treatment of equinia. No specific is known, and no drug which has any favourable influence over its course. Iodine, arsenic, and strychnia have each been recommended. All that can be done, probably, is to support the patient by nourishment, stimulants, and tonics; to relieve pain and other symptoms; and to cleanse, and treat with stimulating or astringent lotions, or other applications, the nasal mucous membrane and other inflamed and ulcerated parts which are within reach. During convalescence change of air and good diet are of course important.

---

## XXII. SYPHILIS

*Definition.*—A specific disorder, communicable only by inoculation, resembling the exanthemata in the facts that it presents a period of latency, and a period during which characteristic eruptions make their appearance, and that one attack confers protection; but differing from them in the remarkably long duration of these periods, and in the tendency to the recurrence, it may be for many years, of specific lesions.

*Causation and history.*—Syphilis has occasionally prevailed in the form of widespread and severe epidemics. One such epidemic passed through

Europe during the latter part of the fifteenth century ; and it was probably in great measure owing to this fact, that for a time it came to be assumed that the disease first made its appearance in Europe after the discovery of America, and had been imported from that continent. There is no doubt, however, that this was an erroneous assumption ; and that, just as syphilis prevails now, so it has prevailed from the earliest times both in Europe and in the other quarters of the Old World. Like many other diseases, syphilis was long confounded with affections which, though often associated with it or arising under analogous circumstances, are essentially distinct from it. Hunter regarded gonorrhœa as one of its manifestations, and even until quite recently other forms of circumscribed inflammation of the surface of the genital organs have been confused with the true chancre—the sore which arises at the point of syphilitic inoculation. But, thanks to the labours of Ricord and other recent observers, including Henry Lee, the phenomena of syphilis apparently have now been fully disentangled from those of the maladies which simulate it, and our knowledge of syphilis is as accurate as is our knowledge of scarlet fever or small-pox. The symptoms of syphilis are quite characteristic, and when fully developed can rarely escape ready recognition ; yet the disease, though maintaining its identity and typical features, has varied very greatly in its virulence at different times and in different countries, under circumstances the nature and relative importance of which it is not easy to estimate. Of the specific nature of syphilis, therefore, there can be no doubt. There is equally no doubt that it spreads by means of a specific contagium, and that there is no evidence to show that it ever originates spontaneously. Lustgarten describes specific bacilli, which resemble those of tubercle and leprosy. The rods present two or more ovoid points in their course, and are always found within nucleated cells. The specific poison of syphilis is never imparted, like that of typhus, by atmospheric conveyance, or, like that of cholera, by means of diffusion through water ; it acts only when directly introduced by inoculation. For the most part it is imparted in the act of sexual intercourse by the secretions which are furnished by primary or secondary sores—the thin cuticular covering of the glans penis and inner surface of the prepuce, and the mucous membrane of the urethra, and the corresponding parts in the female, becoming readily inoculated even when no breach of surface exists. It is also not unfrequently transmitted from the sucking child to its nurse, or from the nurse to her suckling, either from the mucous membrane of the mouth to the nipple, or conversely, or from mouth to mouth. But, indeed, inoculation may take place at any part, provided only the cuticular layer be not too thick, or there be an excoriation or wound ; thus syphilis has not unfrequently been accidentally inoculated on the hands of medical men, and occasionally has been imparted by the operation of vaccination. And, lastly, it is a common thing for syphilitic parents to procreate children who also are syphilitic. Thus a syphilitic mother may have a syphilitic child, the father remaining uncontaminated ; or a syphilitic father may beget a syphilitic child and may infect the mother either directly, or indirectly through the fetus. The

contagium of syphilis resides in its most virulent form, doubtless, in the primary syphilitic sores, and in the indurated glands which succeed to them; but the contagious influence persists during the secondary phenomena of the disease, and also during the period of so-called 'tertiary' manifestations, as is distinctly proved by the fact already adverted to—namely, the transmission of the disease in its later stages from parents to their offspring and from these to healthy wet-nurses. Experiments have been made which seem to prove that the blood of syphilitic patients possesses contagious properties; but there can be no doubt that, as well in the latter as in the earlier stages of the disease, the virus is mainly concentrated in the specific lesions. The secretions of syphilitic patients, more especially the milk, semen, and products of the mucous surfaces, have been supposed to possess infectious properties. But H. Lee is probably right when he insists that only those organs yield infectious discharges which are either distinctly implicated in the syphilitic process or are in a condition of inflammation. The protective influence of one attack of syphilis has only been fully recognised since the true disease has been disencumbered of the maladies which had grouped themselves with it. It is now established beyond doubt: that syphilitic inoculation affords as secure a protection against subsequent attempts at inoculation as does one attack of small-pox or scarlet fever against subsequent attacks of either of these affections; that a person fully under the influence of the syphilitic poison, or who has had an attack from which he has recovered, very rarely acquires a chancre even when inoculated under the most advantageous circumstances, and even more rarely suffers in consequence from the secondary symptoms which so surely follow on the primary inoculation; and, further, that a person inoculated a second time, during the period which elapses between a primary inoculation and the maturation of the primary chancre, has, as the result of his second inoculation, a modified chancre—a chancre which runs its course with exceptional rapidity, and attains its full development concurrently with its elder brother.

*Symptoms and progress.*—1. *Primary symptoms.* When a successful inoculation has been effected on an unprotected person, the virus remains apparently quiescent for a period of uncertain duration, but which is estimated by Lancereaux at from eighteen to thirty-five days, with a mean of twenty-eight days. At the end of that time a minute dusky red papule makes its appearance, which for the most part is unattended with pain or itching, and slowly enlarges. Soon a thin greyish crust, the result of superficial necrosis, forms on its most prominent part. Whilst the papule gradually increases in area, successive crusts are formed and shed from its surface, which thus becomes more and more eroded; so that before long the papule, which has now become a tubercle, displays an elevated dusky red margin surrounding a concave excavation, with a grey dry surface. Almost from the beginning the papule has a remarkably indurated character, and appears imbedded, as it were, in the substance of the skin. These characters it retains, the induration extending a little beyond the area of elevation,

and presenting a very obvious edge, so that the mass can be readily grasped between the finger and thumb. At the end of about six weeks the tubercle has attained its complete development, and is perhaps of the size of half a pea, or somewhat larger. It then begins slowly to subside, and after a while cicatrizes, generally however leaving behind more or less dusky discoloration, induration, and permanent depression. This is the course of the true Hunterian chancre. But, just as the inoculated cow-pox vesicle presents many deviations from its natural course, so does the pimple which results from syphilitic inoculation. For a description of these reference must be made to surgical works. It should be stated, however, that inoculation sometimes takes place without the development of any appreciable local sore, and that a sore may have existed, and yet no visible cicatrix remain.

A week or two, usually, after the first appearance of the chancre, the lymphatic glands in relation with the affected part begin to enlarge. If, therefore, the chancre be on the genital organs the glands of one or both groins suffer. Their enlargement is slow and painless. For the most part several glands are affected, and each probably attains the size of an almond shell. They remain freely movable under the integuments, and are characterised, like the chancre itself, by extreme induration. They seldom undergo suppuration, but remain with little change for months or years.

The period to which the above phenomena belong corresponds exactly to the incubation of the exanthemata, and consequently to that period in the inoculated small-pox during which the primary pustule attains maturity, and which precedes the general variolous outbreak.

2. *Secondary symptoms.*—From six weeks to three months, generally perhaps between sixty and seventy days, after inoculation, the eruptive stage, or stage of secondary symptoms, supervenes. The invasion of this stage is often indicated by slight febrile symptoms, attended with recurring exacerbations, increased frequency of pulse, loss of appetite, weakness and emaciation, cachexia, restlessness, want of sleep, and pains, more or less variable but augmenting towards night, in the head, joints, and back. Shortly afterwards, or sometimes concurrently with the febrile disturbance, phenomena of a more characteristic kind manifest themselves. Among the earliest of these are certain affections of the skin and mucous membranes, and inflammations of the joints, bones, and eyes. The cutaneous affection, which is a form of roseola, generally first appears on the trunk, but before long involves the face and extremities, including the palms and soles. It is in the beginning a mere subcutaneous rash of roundish dusky-red spots, varying from one to two or three lines in diameter, and fading at the edges. But they soon become slightly elevated and lenticular in form. They are variously scattered, but are not unfrequently grouped in segments of circles or in circles. The rash comes out in successive crops, and may continue off and on for some two or three months. In association with it the hair not unfrequently gets dry and loses its gloss, and presently begins to fall out; and thus more or less complete baldness is apt to ensue. This roseola may

be the only rash to make its appearance, but very commonly it constitutes the first stage of some other variety of skin disease. Thus, sometimes the individual roseolous spots, or the patches formed by the coalescence of several, gradually enlarge, and fading away in the centre form circles or irregularly rounded margined tracts of erythema circinatum; sometimes as they enlarge they get covered with thin scales, and acquire a close resemblance to lepra or psoriasis; sometimes they assume the form of distinct but flat tubercles; sometimes they become the seat of vesicles or blebs, and occasionally even of pustules. And hence the secondary eruption may acquire an erythematous, scaly, papular or tubercular, vesicular or pustular condition, or may present several or all of these characters at the same time variously combined. But besides this peculiar polymorphous character, which of itself points to syphilis, there are generally certain peculiarities about the eruption which, apart from all other considerations, indicate its specific character. In the first place, it often presents a peculiar dusky-red or coppery tint, which is due to some pigmentary deposit in the substance of the cutis, and tends to persist long after the actual eruption has disappeared. Occasionally the course of the superficial veins in the extremities, and especially along the shins, becomes mapped out by similar dusky pigmentary stains. This condition is not peculiar, however, to syphilis. In the second place, syphilitic eruptions have a singular aptitude to affect those parts which the non-specific eruptions they resemble specially avoid; they are common on the flexor aspects of the joints, about the forehead, where they often cause the so-called 'corona veneris,' and especially in the palms and soles. It may be added that, in syphilitic lepra, the formation of scales is usually much more scanty than in the non-specific variety of the disease; that it is almost impossible to make any real distinction between the several syphilitic affections of the palms and soles, inasmuch as all are generally attended with desquamation; and that scabs, due apparently to the interstitial effusion of serum or pus, sometimes form on leprous or tubercular patches, which thus pass by easy gradations into the truly vesicular and pustular conditions.

The morbid processes of the mucous membranes first show themselves in the fauces and pharynx, generally upon the tonsils. On the last, which then present an inflammatory blush, shallow ulcers, for the most part reniform in shape, make their appearance; they are generally unattended with pain or even uneasiness, and disappear after a few weeks. Similar sores are also apt to form on the palate and internal surface of the cheeks, on the tongue and lips. In addition, condylomata or mucous tubercles often become developed in the mouth, fauces, and pharynx, about the anus, upon the mucous or delicate cuticular surface of the genital organs, and in those parts of the skin which are in constant apposition and consequently always moist. Mucous tubercles are roundish, oval, or irregular congested tabular elevations, not fibrous, warty, or villous, but uniform in texture and soft, with a tendency to be covered with a greyish or yellowish film, to exude abundant moisture, and to secrete pus, or undergo ulceration. Similar formations may arise in the rectum, œsophagus, nose, larynx, trachea,

and bronchial tubes, and not improbably in other parts of the mucous tracts.

The pains in the joints and bones are of a rheumatic character, and are apt to be specially severe at night. There may be no visible change in the parts affected; sometimes, however, there is obvious periostitis, or arthritis and effusion into the joints. True nodes are comparatively seldom developed at this time.

The affections of the eyes are twofold. The more obvious is a form of iritis, attended with little pain, uneasiness, or intolerance of light, but with more or less of the ordinary form of sclerotic injection which accompanies iritis. Exudation of rust-coloured lymph occurs at the surface of the iris, mainly, however, at its inner margin, and, though much less frequently, at its outer margin. In the former situation the lymph may form a uniform tumid ring, and in either situation a series of reddish beads. At the same time the iris becomes sluggish or immovable, and probably adheres to the surface of the lens, and the aqueous humour gets turbid and yellowish from admixture with inflammatory products. The less obvious but more serious form is retinitis, coming on insidiously without external congestion, pain, or intolerance of light, but marked by increasing haziness of vision and indications of retinal congestion and extravasation.

3. *Tertiary symptoms.*—The period of secondary symptoms, after lasting for a few weeks or months, terminates for the most part in spontaneous convalescence, and the patient may possibly remain henceforward free from disease. But more commonly, after the lapse of an uncertain period, generally from six months to two years, but sometimes twenty years or more, other characteristic lesions manifest themselves, distinctly referrible to the syphilitic poison, and usually termed tertiary symptoms. Although, however, there is generally a distinct interval between the subsidence of the secondary and the onset of the tertiary symptoms, they do occasionally, and perhaps not unfrequently, become intermingled, or pass without break one into the other. The chief characters by which tertiary symptoms are distinguishable from those of earlier occurrence are: first, their dependence on a specific overgrowth of tissue—the formation of gummata; second, their great inveteracy and tendency to recur; third, their involvement of internal organs as well as of parts that are superficial; and, fourth, their want of symmetry. Febrile temperature not uncommonly attends the progress of tertiary syphilis, and is sometimes very persistent, and of characteristic hectic type. We will consider the more important of the lesions above enumerated *seriatim*, and in reference to the organs which they affect.

a. *Skin.*—The most common form of skin disease is characterised by the appearance of dusky red or coppery flat tubercles, which differ little, if at all, in the first instance, from those described among the secondary symptoms; they are, however, generally larger, more prominent and more indurated, and occur sometimes widely scattered, sometimes collected into irregular groups, sometimes arranged in the form of crescents, circles,

or sinuous lines. In the first case they gradually increase in number, and coalesce; in the second, the groups tend to grow in area, and not unfrequently also in thickness, so as to form irregular tuberculated elevations of considerable extent and thickness; in the last case the affection tends to spread centrifugally, slowly invading the healthy surface by a line of ever-new tubercles, while the parts primarily affected return to a state of comparative health. In some instances the tubercles become scaly on the surface, the affection presenting a certain amount of resemblance to some forms of lepra; in other instances they undergo superficial molecular necrosis, they get more or less deeply eroded, and a scab forms without a vesicle or pustule having ever been developed; in other cases each papule undergoes suppuration, and a thick adherent ecthymatous scab results; and lastly, ulceration is not unfrequent. But, whichever of these processes takes place, the disappearance of the active lesion is always followed by the formation of indelible depressed cicatrices; and the progress of the serpiginous form can always be traced by the cicatricial surface which it leaves in its wake, and the pre-existence of large patches always recognised by the persistence of a corresponding cicatrix. The tubercular eruptions here described, although essentially identical with one another, are often denominated, according as one or other peculiarity predominates, tubercular, pustular, or serpiginous syphilide, or syphilitic lupus, or psoriasis. They affect almost any part of the body, but are perhaps especially common on the face, neck, and shoulders, buttocks and extremities. When they occur, as they frequently do, on the palms and soles, there is little to distinguish them from secondary lepra. Another well-marked form of skin-affection is that known by the name of syphilitic rupia. It consists in the scanty formation, indiscriminately on various parts of the body, of isolated blebs, each of which arises on a congested indurated base, and may attain the diameter of a threepennypiece. Their contents are clear and limpid, or turbid and sanious, and soon concrete into scabs, each of which, from constant additions to its edges and base, rapidly attains large dimensions: a thickness, for example, varying from a quarter to three-quarters of an inch, and a form which may resemble that of a limpet-shell or oyster-shell, or may be merely irregular and rocky. The base at the same time becomes deeply excavated, and on removing the scab a deep unhealthy slow-healing ulcer is revealed. These rupial sores leave remarkably deep cicatrices.

Very frequently, altogether independently of any primary cutaneous disorder, hard nodules, from the size of a pea to that of a filbert, appear singly or in groups in the substance of the subcutaneous connective tissue. They are unattended with pain, and very slow in their progress; but after a while they adhere to the skin, which then becomes somewhat prominent over them, assumes a dusky red tint, and gives to the fingers a sensation of elasticity and resistance, or of 'bogginess.' Before long the central portion of the involved skin becomes perforated in one or more points, and a viscid, turbid, or sanious fluid escapes, together with shreds or a mass of subcutaneous slough. In this way a deep cavity results, the

boundaries of which are formed of ragged greyish or yellowish tissue. If groups of these masses soften, we get a number of such cavities side by side, the skin appears irregularly honeycombed, and the bridges which intervene between the adjoining openings get undermined by the coalescence beneath them of the contiguous cavities. Thus extensive and deep destruction of skin and subcutaneous connective tissue takes place, which is very slow of repair, and followed by deep cicatrices.

*b. Mucous membranes.*—The affections of the mucous surfaces have much resemblance to those of the skin. They are chiefly superficial and tubercular, or sub-mucous and gummatous. The former are especially frequent on the tonsils, fauces, soft palate, pharynx, tongue and other parts of the mucous surface of the oral cavity, and in the larynx; are followed by deep unsymmetrical and obstinate ulceration; and lead to extensive destruction with permanent loss of tissue and contraction. Thus, the uvula and soft palate may be more or less perfectly destroyed; the isthmus of the fauces may be narrowed; stricture of the œsophagus may ensue; or destruction of the epiglottis, vocal cords, or other parts of the cartilaginous skeleton of the air-passages may take place; and, following upon these several lesions, loss of voice, difficulty of swallowing or breathing, and other serious or fatal consequences. Gummatous tumours also appear in the same parts, frequently in the tongue, where they may attain the size of a hen's egg, and sometimes in the connective tissue and muscles of the larynx. These not unfrequently assume many of the superficial characters of epithelioma, and undergo the same processes as do subcutaneous gummata.

Similar affections to the above take place in the male urethra and in the vagina and os uteri, as well as in the external parts of the organs of generation of both sexes; they also occur within the anus and in the lower part of the rectum; and may in all of these situations, in addition to other forms of mischief, lead ultimately to more or less serious contraction or stricture.

*c. Organs of locomotion.*—Voluntary muscles are occasionally affected in the same way as the subcutaneous connective tissue. Gummata invade their texture, separating from one another their fibres, which then undergo degeneration. Such growths occur quite irregularly and may be mistaken for tumours of a far more serious character. We have already pointed out that they may form among the muscles of the larynx; they have also been observed implicating the masseter, the muscles of the scapula, and indeed those of most other parts. The bones are sometimes affected with diffused periostitis; but more commonly nodes are developed on various parts of the long or flat bones, including the ribs, sternum, and bones of the face and skull. Nodes are gummatous growths in connection chiefly with the periosteum. They are usually extremely painful and tender, of various extent and prominence, more or less hard and unyielding at the periphery, but elastic or even fluctuating in the centre. They seldom end in suppuration, and generally on healing leave some irregularity behind. Nodes do not usually result in caries or necrosis. A more frequent cause

of these conditions is the extension of syphilitic ulceration in depth until subjacent bone is involved. But from one or other of these causes caries or necrosis may attack any bone; the bones most frequently thus affected, however, are those of the nose, palate, and skull, to which may be added the cartilages of the larynx and trachea. The bones of the ear also may suffer. Syphilitic affections of the skull are generally limited to the outer surface and diploe, but occasionally involve the inner table as well, and are then apt to cause more or less serious cerebral symptoms. The joints occasionally suffer, the surrounding soft parts becoming thickened and infiltrated, and the cavities distended with fluid effusion.

*d. Viscera.*—The affections of the internal organs are scarcely so well known as those of the parts which have already been considered, but they are even more serious. The liver is perhaps their most frequent seat. The chief conditions which have been recognised here are, first, a more or less general hyperplasia of the connective tissue, especially of the capsule of Glisson, leading to a variety of cirrhosis; and, second, the formation of gummy tumours which rapidly undergo degeneration, and by their contraction cause puckering and fissuring of the surface of the organ. Either of these conditions may lead to the development of symptoms identical with those resulting from ordinary cirrhosis. The organs of circulation also are frequently implicated. The muscular tissue of the heart is occasionally the seat of diffuse fibroid infiltration or of more or less extensive gummatous formations, exactly like those involving the voluntary muscles. These induce degeneration of the tissue, induration, adhesion of pericardium, and the ordinary symptoms of progressive cardiac incompetence. There is good reason also to believe that some forms of arterial disease, and especially that form in which the inner coat undergoes a kind of nodular hypertrophy antecedent to the supervention of degenerative changes, are in many cases the result of syphilis. It is at all events certain that arteries frequently assume this condition in those who are the subjects of syphilis, and who are suffering from gummatous tumours in other organs. And it is also certain that some of the lesions observed in the brains of syphilitic patients are essentially due to arterial changes of this kind, involving, however, not only the internal coat, but the adventitia, and to some extent also the middle coat, and leading to obstruction either directly or by thrombosis. Syphilitic affections of the lungs (gunmata and fibroid infiltration) are described; nevertheless, their recognition is attended with much uncertainty. We have already adverted to the fact that the bronchial tubes, like the larynx, may be distinctly implicated. But, besides bronchial lesions, there are not unfrequently found in the lungs of old syphilitic patients scattered masses of hard greyish or blackish fibroid induration, or caseous masses imbedded in such tracts of induration, which, although in many particulars resembling affections of tubercular or inflammatory origin, are almost certainly gunmata. The most grave of all tertiary syphilitic affections are those which involve the nervous centres. Gummatous tumours are developed in connection sometimes with the inner layer of the dura mater, sometimes

with the pia mater, or the connective tissue of the brain-substance. In the latter two cases the growths, which may attain the size of a pigeon's egg or even of a hen's egg, are, even if of peripheral origin, for the most part imbedded in the substance of the brain. Their most frequent site is the basal portion. Similar growths occur, though much less frequently, in connection with the spinal cord. The symptoms due to them are those of cerebral or spinal tumours. The cranial nerves and even the brain-substance are occasionally the seats of syphilitic infiltration. Specific affections of the kidneys have been less thoroughly investigated; nevertheless, it is certain that these organs are sometimes attacked, sequentially to syphilis, with diffused inflammatory processes, which induce atrophy, and that they are sometimes studded with distinct gummata or with patches of cicatricial tissue, attended with corresponding linear or stellate contractions of the surface, and having imbedded in them small caseous masses. The testes are frequent seats of gummata, and also of diffused inflammatory processes. They are apt to become much enlarged; occasionally suppurate; and not unfrequently are associated with hydrocele. The lymphatic glands, as has already been pointed out, get enlarged and indurated secondarily to local syphilitic lesions; but occasionally, here and there in groups, they acquire such enormous dimensions as to simulate the enlargement of these organs due to scrofula, lymphadenoma, or cancer. Among other organs liable to syphilitic disease may be enumerated the spleen, stomach and bowels, mammæ, and organs of special sense.

The effects of syphilis do not end here. The long persistence of tertiary symptoms, with their frequent tendency to relapse, leads gradually but surely to a marked cachectic state of the system, indicated by sallowness and anæmia, with relative increase of white corpuscles, emaciation and loss of strength, and lardaceous or amyloid degeneration of the liver, spleen, kidneys, and other parts, together with the additional symptoms to which such complications give rise. And finally may follow, tuberculosis, or insidious but non-specific inflammations of various internal organs.

4. *Inherited syphilis* presents some peculiarities which make it necessary to give the subject a brief separate consideration. It may be derived from father or mother, or from both. The effects of parental syphilis are not unfrequently manifested in the death of the fœtus, and consequent abortion, at the latter period of pregnancy. The child is born dead, and more or less decomposed, but usually without distinct evidence of specific taint. In some instances, however, the placenta is affected with syphilitic disease. In other cases the infant is born alive, but shrivelled, puny, and unhealthy-looking; and large bullæ appear on the palms, or wrists, or the corresponding parts of the lower extremities. These blebs give rise to unhealthy sores, and the infant almost invariably dies speedily. In the majority of cases, however, the babe appears to be healthy at birth, and first gives evidence of disease after an interval of three or four weeks. The symptoms are mainly those of the secondary period of acquired

syphilis; but there are some features which are specially characteristic and important, and to these alone attention will now be drawn. Among the earliest of these are, congestion and swelling of the nasal mucous membrane, with abundant secretion, giving rise to snuffles and other symptoms of chronic coryza; diffuse inflammation of the mouth and fauces, with sores at the angles of the mouth; mucous tubercles about the anus and similarly constituted parts; and a roseolous rash. The rash is generally most abundant on the buttocks, privates, and neighbouring parts of the abdomen and thighs, on the face, and on the palms and soles. It consists in circular patches from a line to half an inch in diameter, which either form lenticular elevations, or are slightly concave or cupped, and present therefore a more or less tumid marginal ring. They vary in colour, are sometimes dusky red, sometimes brown or yellow, sometimes of a more or less coppery tint. They may be smooth or scaly, or may present superficial excoriation or erosion. The eruption on the palms and soles assumes a scaly character, and is attended with a tendency to crack and exfoliate. In association with the above phenomena the child becomes emaciated, its face assumes an old and weird character, its complexion grows sallow and unhealthy-looking, its skin dry and shrivelled, its hair scanty and thin, and not unfrequently it suffers from diarrhoea. These symptoms last probably for a few months, and have generally disappeared by the end of the first year. From a few months old to the first or second year syphilitic children are apt to suffer from various affections of the bones of the skull, namely cranio-tabes characterised by softening of the bones, and thinning or disappearance of bone at certain points, more especially where exposed to pressure, diffused thickness of the bones, often associated with cranio-tabes, and the appearance of nodes or bosses. Somewhat later, generally from the age of four or five up to that of puberty, the tertiary series of symptoms manifest themselves. These differ little from those which characterise the common tertiary stage. There are two or three, however, of peculiar and special interest, which now become apparent or develop themselves for the first time. One of them is flattening of the bridge of the nose, from sinking in of the subjacent cartilages. Another is enlargement of the lower end of the humerus between the epiphysis and shaft. A third is a peculiar form of atrophy of the permanent incisor and canine teeth. This is generally most marked in the upper two central incisors, and is often limited to them; they are atrophied, peg-like, and present towards their free edge a reniform or cordate character—the notch occupying the centre of this edge. This condition is traceable to the effect, on the tooth-germs, of the stomatitis from which the children have previously suffered. The last of them is interstitial keratitis, that is, an interstitial inflammation of the cornea, marked by increasing cloudiness and opacity of the part, and attended with a vascular zone in the sclerotic, and intolerance of light. There is no vesication or ulceration, and the opacity speedily diminishes under appropriate treatment. The recognition of the last two affections is due to J. Hutchinson.

It would be impossible in a brief space to discuss the differential diagnosis of syphilis. It must be sufficient to say that the manifestations of syphilis stimulate a vast range of different diseases; and further that syphilis necessarily often occurs in persons who are the subjects of skin affections and various other disorders, and often exerts a modifying influence over these; and that hence it is frequently quite impossible to form an exact diagnosis without going fully into the history of the

FIG. 37. MALFORMATION OF PERMANENT TEETH IN INHERITED SYPHILIS (Hutchinson).

patient's case, and taking into careful consideration all the facts of his past history and present condition.

*Morbid anatomy and pathology.*—In the foregoing description of the phenomena and sequelæ of syphilis we have necessarily, to a large extent, discussed the pathological processes of the disease and its morbid anatomy. It remains, however, to give a brief connected account of these subjects. The morbid poison which enters the system at the time of inoculation is doubtless a living entity or contagium, which imparts specific properties, primarily to the growth which it directly induces, and secondarily to the vital constituents of the enlarging lymphatic glands situated next above that growth. Possibly from the primary sore, more probably, however, from the group of morbid lymphatic glands, as a centre, is shed into the blood-stream newly manufactured contagious matter (probably particulate); which in its turn infects in different proportions and in different order the various organs and tissues of the body, producing in them specific processes which have a more or less close resemblance to those out of which they arose, and which like them are infectious certainly to other persons, and probably like carcinoma to the individual. The early series of general phenomena (those for the most part which belong to the period of secondary symptoms) differ scarcely at all in their anatomical characters and in their local results from simple inflammatory processes. There are congestion, proliferation of connective tissue imitative of granulation tissue, and a tendency in the new formation, after a temporary persistence, to subside altogether so as to leave no trace whatever behind, or to merge into the tissues in relation with which it appears: if in relation with connective tissue, into connective tissue, if in relation with bone into bone, if in the matrix of the liver, kidney, lung, testicle, or brain, into nucleated fibrous tissue, and to produce therefore in these organs induration, contraction, and atrophy. The later phenomena (those which belong chiefly to the tertiary stage) consist in the formation of adventitious growths, termed gummata, which are identical in structure with primary chancres and the primarily indurated glands. They consist like them of cell growth, differing little microscopically from ordinary granulation-tissue, and in this respect therefore little from the secondary lesions, but presenting certain special

features. Thus they do not so much displace as infiltrate or involve the tissues among which they arise; they have a remarkable tendency to undergo speedy caseous degeneration and to cause molecular or fatty disintegration of the higher elements which are mixed up with them; if developed in internal organs, they acquire for the most part permanence as caseous lumps, earthy concretions, indurated fibrous patches, or morbid tracts in which all of these conditions are variously combined; and if they be developed in superficial parts, such as the skin, mucous membranes, or superficial bones, their degeneration results in the formation of crusts, ulcers, abscesses, or sloughs, with more or less serious destruction of tissue. Gummatous tumours, while in process of development, vary in their physical characters; thus, sometimes they are greyish, firm, translucent, or opaque; sometimes (especially when they form beneath the skin and mucous membranes) they are infiltrated with a mucus-like fluid, which oozes away when they are laid open.

There is undoubtedly a resemblance both anatomically and functionally (at all events as regards their infectiveness) in all the congestive or proliferating lesions which depend for their origin on the syphilitic virus. And although a line may be drawn, both on clinical grounds and for the purposes of description, between secondary and tertiary phenomena, and although it is quite true that the later lesions are far more serious and virulent than those which precede them, there is no doubt that they pass one into the other, that they shade off the one into the other by numerous gradations, and that they are often blended; so that while, on the one hand, gummatous tumours may occur during the secondary period, secondary eruptions may be met with later in the progress of the disease.

*Treatment.*—For the prophylactic treatment of syphilis, and for the treatment of the primary affection, reference must be made to surgical works. The inoculation of syphilis upon healthy persons, which has been so extensively practised by Boeck, and advocated by others, in order that by giving them the disease it might affect them in a mild form and prevent any future attack in a graver form, seems to us, we confess, not only dangerous but altogether unjustifiable. It is now generally admitted that syphilis, like other specific febrile diseases, is incapable of absolute cure, and that it will run a definite course in respect of duration, no matter what steps are taken to arrest its progress. It is nevertheless certain that we have at least two remedies which exert a remarkable influence over its various localised manifestations, which subdue them almost to zero if they do not absolutely annul them, and which keep the general disease in abeyance even if they fail (as they probably do) to extinguish it altogether. These remedies are mercury and iodine in their various preparations. The value of mercury was early established, and has indeed only lately been regarded with suspicion. But this suspicion arose doubtless out of the injurious influences which the abuse of mercury engendered during the early part of this century, and was supported by the recognition of the fact that the free use of mercury failed in many

cases to prevent the supervention of secondary symptoms. It is admitted now that mercury does not prevent either secondary or tertiary symptoms from coming on ; but nevertheless it is certain that it has a marvellous influence in causing the removal, in turn, of the primary, secondary, and tertiary lesions of the disease. The form, the dose, the mode, and the length of time in which the drug should be administered are points on which there is much difference of opinion. Some prefer to introduce it by the inunction of strong mercurial ointment on the inner aspect of the thigh or other parts in which the integuments are thin : in this case from half a drachm to a drachm of the ointment may be rubbed in every night before the fire. Others affect the practice of fumigation by means of volatilising calomel with the heat of boiling water. The drug may by this means be inhaled, or applied to the general surface, or to particular regions with little difficulty. For inhalation, not more than four or five grains of calomel should be employed. Others again recommend that the mercury should be administered by the mouth. For this purpose any mercurial preparation in an appropriate dose is applicable. But the most convenient, and possibly the best, is corrosive sublimate or red iodide of the mercury, of which from  $\frac{1}{20}$  to  $\frac{1}{8}$  gr. may be given three times a day, or equivalent doses of the *liquor hydrargyri perchloridi*. The treatment should be continued until the lesions have disappeared under its influence, and even for a week or two longer, and the quantity should be regulated by its effect on the system, slight soreness of the gums only being maintained. Iodine is almost equally valuable with mercury ; but it seems to have a special value during the later periods of the disease, in which (when the lesions prove intractable) it may often be beneficially combined with the mercurial treatment. The usual, and probably on the whole the best, form is the iodide of potassium in from 5 to 10 grain doses three times a day, combined with a tonic. The syrup of the iodide of iron is very valuable in many cases, and especially for young children. Bromine has an antisypilitic power similar to that of iodine, and is sometimes substituted for it. Among other anti-venereal remedies which have acquired and still enjoy a wide reputation are sarsaparilla, and nitric acid in large doses. They have probably no specific virtues at all. Tonic medicines (quinine, iron, cod-liver oil, and the like) are often of immense value in the treatment of the cachexia which attends the later stages of the disease. The value of local applications to syphilitic lesions is undoubted : the most important of these are the mercurial and the iodic, among which may be enumerated powdered calomel, black-wash, mercurial, citrine, or iodine ointment, iodide of starch paste, and localised calomel fumigations—one or other being employed according to the nature of the lesion, and the convenience and relative safety of its applicability.

XXIII. PYÆMIA (*Septicæmia*)

*Definition.*—By ‘pyæmia’ is understood a febrile and generally acute disorder, due to the entrance into the blood of certain poisonous or septic matters, for the most part in connection with unhealthy inflammations, and usually characterised by the blocking up by clots or emboli of the arterioles of the lungs and other organs, and by the consequent occurrence therein of scattered patches of congestion, hemorrhage, inflammation, suppuration, or gangrene. The terms ‘septic poisoning’ and ‘septic infection’ have been applied to those cases in which, while septic matters are absorbed and cause febrile symptoms, no blocking of arterioles ensues, and the secondary lesions characteristic of pyæmia are not developed.

*Causation.*—The conditions out of which pyæmia arises are very numerous and various. First, it is a frequent sequela of accidental fractures, especially of the long bones, and of the bones of the head and pelvis. Second, it frequently ensues on surgical operations, especially those attended with the formation of extensive raw surfaces such as amputations of the larger limbs, and also those involving bone, bladder, prostate, urethra, or rectum. To these must be added operations on veins, such as phlebotomy and operations for the cure of varicose veins and hemorrhoids. Third, pyæmia occurring after parturition constitutes one of the most common and fatal forms of so-called ‘puerperal fever.’ Fourth, pyæmia not very unfrequently originates in acute suppurative inflammation taking place at the surface or in the substance of bones—cases in which, as a rule, the periosteum becomes extensively detached, and the bone necrotic. Fifth, it often arises in the course of chronic diseases of bones, especially perhaps of those of the middle and internal ear. Sixth, many varieties of so-called unhealthy inflammation, such as erysipelas, diffuse cellular inflammation, carbuncle, and dissection-wounds, are often fatal on account of the supervention of this complication. When pyæmia manifests itself after injuries or operations, it is generally preceded by some obviously unhealthy condition of the implicated tissues. Also it is far more liable to originate in affections of certain organs and tissues than in those of others. Among these may be included the connective tissue generally, the bones, the male and female pelvic organs, and the veins. That pyæmia is in a large number of cases imparted by contagion is beyond dispute. It is thus that it often spreads in the surgical wards of a hospital, and among the puerperal inmates of a lying-in institution. In all such cases there is good reason to believe that it is transmitted from patient to patient by direct inoculation at the raw surfaces of wounds or of the placental area; or rather, not so much pyæmia is transmitted directly from patient to patient, as some form of erysipelatous or other unhealthy inflammation is thus transmitted, of which pyæmia is a common accident. It is certain, on the other hand, that even when it complicates the puerperal state and surgical wounds, it often arises, so far as we can discover, *de novo*. It still remains to

consider whether there are any special conditions of system and of a patient's surroundings which render him peculiarly liable to become pyæmic. In reference to this point it may be remarked that age and sex have no distinct influence; that patients, apparently in the best of health, are often stricken with pyæmia; and indeed, that when pyæmia pervades a ward, it by no means selects the weakly and the cachectic in preference to the robust and healthy-looking; and again, that it does not arise with special frequency in connection with simple overcrowding, bad ventilation, or common filth.

So far as we know, the related conditions included under the term septicæmia, namely septic poisoning and septic infection, originate under the same circumstances as pyæmia itself; and all are due, as we have previously shown, to the influence of septic bacteria.

*Morbid anatomy and pathology.*—The post-mortem phenomena which characterise the presence of pyæmia are (as stated in our definition of the disease) patches of congestion, hemorrhage, inflammation, suppuration or gangrene, disseminated more or less abundantly throughout the organs and tissues of the body. These are most common in the lungs, and are often confined to them. We find here, irregularly scattered but mostly abutting on the surface, circumscribed patches ranging from the size of a pea to that of a walnut. These are sometimes distinctly apoplectic, in which case they may be reddish-black or more or less decolourised, solid or partly broken down into a puriform pulp; sometimes they present the ordinary characters of lobular pneumonia; sometimes they are simple abscesses or gangrenous cavities. These different characters depend in part no doubt on the stage at which death has taken place, but are often due to individual peculiarities. There is usually more or less congestion and œdema of the general lung-tissue, and occasionally diffused pneumonic consolidation and secretion of mucus into the bronchial tubes. There is probably always a deposit of pleural lymph over and around each pyæmic lump which involves the surface of the lung; and not unfrequently general pleurisy ensues. Sub-pleural petechiæ are common. The surface of the heart, like that of the lungs, is often studded with small extravasations of blood; as also are the substance of the cardiac walls, and the sub-endocardial tissue. And sometimes, generally in relation with these extravasations, small yellowish patches of disintegrating tissue or abscesses may be discovered. When these reach the inner or outer surface of the heart they are apt to provoke inflammation of that surface. Neither pericarditis nor endocarditis is of rare occurrence. Of the abdominal organs, the liver, spleen, and kidneys most frequently suffer. In the liver, generally in connection with patches of congestion or of anæmia, we sometimes find small buff-coloured spots of disintegrated tissue, sometimes abscesses of considerable size full of greenish purulent fluid. The morbid conditions presented by the spleen and kidneys are almost exactly such as are met with in embolism or thrombosis of the vessels of these organs. In the spleen we observe apoplectic or fibrinous blocks of various sizes, which have often undergone more or less disintegration and

softening, or even conversion into abscesses. The kidneys are sometimes studded (chiefly in the cortex) with small abscesses, grouped for the most part in lines perpendicular to the surface and surrounded by a halo of congestion. Occasionally no abscesses have formed, but almost the whole of their tissue is mapped out by tracts and bands of deep congestion, which alternate with and surround patches of which the colour is unnaturally pale. Spots of hemorrhage, patches of inflammation, or small abscesses may be present in any other of the abdominal organs, sometimes, for example, in the intestinal wall; and the peritoneum may be affected exactly in the same way as the pleuræ and pericardium. The brain is not very commonly the seat of pyæmic changes; extravasations of blood are generally small in amount and limited to the surface; patches of softening exactly like those due to embolism, excepting that they rarely exceed the size of a horse-bean, may occur in any part of the organ; abscesses containing greenish-yellow glairy pus attain a much larger size. Meningitis also occurs. The bones and joints are frequently involved. The secondarily affected bones rapidly become denuded of periosteum, fetid pus accumulates upon their surface and probably in their substance, and rapid necrosis ensues. The synovial fringes of the joints get intensely congested, and the synovia increased in quantity or replaced by pus or puriform fluid. The cavities of the joints become distended, and the parts around inflamed. It is important to bear in mind that suppuration may occur in the neighbourhood of joints without involving them, and that pyæmic inflammation of joints is not always suppurative. It must be added to the foregoing account that secondary inflammations, suppurative or not, frequently manifest themselves in the connective tissue and among the muscles; and that of organs which have not been specially named, the eye, the prostate, and the testis are very apt to suffer. The skin never presents any characteristic change; but it is often slightly jaundiced, and occasionally presents petechiæ; sudamina are common.

The condition of the blood and blood-vessels in pyæmia is a matter of great interest. The bulk of the circulating fluid, and the vessels in the greater part of their extent, have usually the aspect of perfect health. The coagula, indeed, which are found post mortem in the heart and larger vessels usually differ in nothing from coagula found under other circumstances; very rarely a few soft masses of disintegrated fibrine or of corpuscles resembling pus may be found imbedded in them. But, with this exception, it is only in the arteries which lead to the secondary morbid patches, and in the veins involved in the primary lesion, that visible morbid phenomena are present. The minute arteries distributed to each patch of pulmonary disease are always found filled and obstructed either with ordinary thrombi or with a soft yellowish material, consisting of disintegrated fibrine and corpuscles, or in some cases of these mingled with what appear to be groups of pus-cells. Similar coagula have been detected in the small vessels leading to the diseased patches occurring in the heart, spleen, and kidneys, and doubtless are always present in the arteries, which

are connected with the generalised pyæmic lesions. The veins which are involved in the primary inflammatory process are in a very large proportion of cases obviously diseased. It is true that, even after careful dissection, they have in some cases appeared to be entirely healthy. But when we bear in mind that in other cases the presence of diseased veins has only been detected after hours of minute investigation, we shall see reason to suspect their existence in cases where they have been reported to be absent. When diseased, their parietes are thickened and indurated; they may be entire, or may communicate by orifices resulting from ulceration or some other cause with the morbid elements in which they are imbedded; and their interior is occupied by coagula. These are mostly adherent, and more or less decolourised; they may be solid throughout, but more commonly are reduced in their interior into a reddish or yellowish pus-like pulp or fluid. This appears generally to consist of disintegrated fibrine, but is in some cases true pus. It is mostly separated from the venous walls by a layer of fibrine, and shut out from the proximal portion of the venous channel, wherein it lies, by a continuation of this layer of fibrine, which forms a kind of diaphragm or septum between them. In some cases no mechanical impediment whatever exists to prevent the free admixture of the pus contained in the vein with the general circulation.

We are now in a position to discuss the proximate cause of pyæmia. It was formerly supposed that the secondary inflammatory patches were mere deposits of pus which had been absorbed as such by the veins and carried to the localities in which abscesses were found. But, unfortunately for this view, pus as such is not found to circulate with the blood, and the secondary patches of disease are never in the first instance, and not often at any time, distinctly purulent. The theory of embolism, however, here comes to our aid. There is no doubt that the secondary foci of disease are almost exactly such as would be produced by embolism of the arteries leading to them; and we find, in fact, that these arteries are really plugged. But we find, further, that these plugs are identical in composition and appearance with the coagulated material which blocks up the veins of the primary inflamed region. It is reasonable, therefore, to assume that the diseased veins are really the sources of emboli, which, becoming impacted in the pulmonary arteries, induce characteristic changes in the parts beyond, and that the phenomena of pyæmia are, therefore, in large measure due to the dissemination in pellets of the morbid matters (pus, disintegrated clot, and the like) which these veins contain. In favour of this view are the facts that such pellets have been recognised *in transitu*, and that pyæmia is especially liable to occur where veins have been the subject of operation, and where inflammation attacks parts in which the veins are abundant and large, thin-walled, or incapable of collapsing—such parts, for example, as the contents of the pelvis, the uterus after parturition, the cancellous structure of bones, and the meninges of the brain. There can be little doubt indeed of the correctness of the above explanation, so far as it goes, and little doubt also that the quality of the emboli has a marked influence over the quality of the processes which

they induce ; and that hence whether these latter be gangrenous, suppurative, or simply inflammatory, depends in no small degree on the special nature of the process going on in the primary seats of disease. But will embolism alone explain all the phenomena of pyæmia ? To this question Virchow replies in the negative. He considers pyæmia to be a twofold disease, comprising, in the first place, phenomena due to embolism, and, in the second place, phenomena due to the absorption of some more subtle poison. The latter, which he regards as the more important, have been collectively termed *septicæmia*, and he considers that these two groups of phenomena may occur independently of one another. A very strong argument in favour of this view is the fact that patients occasionally die with many of the ordinary symptoms of pyæmia, arising from some unhealthy wound, in whom no morbid conditions whatever can be discovered post mortem, save congestion of various internal organs, small extravasations of blood beneath the serous membranes and elsewhere, and tendency to rapid decomposition. Such cases, which are very acute in their progress, are not unfrequently met with in the course of the endemic prevalence of pyæmia, and are regarded by many as cases in which death has supervened before the specific lesions have had time to develop themselves. The discovery of bacteria in the blood and morbid tissues of pyæmic patients is a matter of deep interest. Indeed, there can be no reasonable doubt that in these organisms we have the specific cause of the disease ; that it is to their abundant presence in the part primarily affected that local unhealthy action is due ; and that it is to their distribution, in association to a large extent with emboli, that the secondary lesions owe their specially unhealthy features, and the general symptoms of disease assume so grave a character.

In conclusion we may say, so far as our present knowledge goes : that septic bacteria (at present indistinguishable from one another) are the causes alike of true pyæmia, of septic infection, and of septic poisoning ; that (as we have already shown) in septic poisoning the bacteria grow only at the primary seat of disease, and evolve there a fluid poison which undergoes absorption ; that in septic infection (as we have also shown) the bacteria infect the organism and multiply in the blood and in the tissues ; and that in true pyæmia we have not only bacterial infection, as in the last case, but disseminated foci of inflammation due to arterial obstruction. It is easy to understand from this view how it is that, when pyæmic processes are present, the lungs are, as a rule, affected both earlier and more extensively than other organs.

*Symptoms and progress.*—The symptoms which usher in an attack of pyæmia are generally well marked, unless the condition of the patient or the nature of the disease under which he is labouring at the time confuses them. The first symptom to attract attention is almost without exception a sudden, severe, and prolonged rigor, followed by profuse perspiration. The patient on recovering from this may for a time appear to be restored to health. But before long, it may be the next day, or at some earlier period, the rigor returns with its after sweating stage ; and again and

again, at varying intervals, rigors and sweats recur. In the course of a day or two the conjunctivæ and skin assume a sallow tinge; the patient becomes dull and heavy, or it may be restless, and acquires very much the manner and aspect of a person suffering from some form of continued fever. In company with the above symptoms, or in succession to them, others of more or less importance show themselves. The pulse becomes rapid, weak, and perhaps intermittent. The tongue becomes glazed and fissured, or coated, and after a time dry and brown, the lips parched, the teeth covered with sordes. The patient is thirsty, loses appetite, suffers often from nausea and vomiting, and not unfrequently from diarrhœa. The respirations become shallow and frequent, and the respiratory acts attended with dilatation of the nares or separation of the lips, and a sniffing, sipping, or sucking sound. Cough often supervenes, attended probably with pains in the chest, and evidences of pleurisy or consolidation of the lungs, and of excessive secretion into the bronchial tubes. The skin, in the intervals between the perspirations and rigors, is often dry and harsh, and may present sudamina. The sallowness generally increases, and often amounts before death to well-marked jaundice. Pain and swelling in or around joints, or in other parts of the connective tissue, often present themselves, and pus may form rapidly in these situations. As the disease advances the patient becomes excessively prostrate, his face shrunken and for the most part pale, his mental functions disturbed; slight delirium comes on, sometimes coma, sometimes convulsions; and death ensues usually in from four to ten days. Sometimes pyæmia takes a more chronic course: the symptoms are then altogether less strongly pronounced, the fever assumes the characters of hectic fever, abscesses form in connection with bones, in the joints and other superficial parts, and the patient sinks from exhaustion at the end of a few weeks or even a few months, or in rare cases recovers after a protracted convalescence. In these cases there is a curious tendency to the occurrence of suppurative pericarditis; and in these especially joints are apt to inflame from time to time, and to subside without suppurating, as in acute rheumatism.

We will consider some of the symptoms of pyæmia more in detail.

The patient's aspect may at first be healthy-looking or nearly so, but soon becomes dull and oppressed. The face is sometimes flushed, sometimes pallid, and often these conditions alternate. Towards the close of the disease pallor generally becomes established, and the countenance shrunken and anxious, or of that dull expressionless aspect which is common in the last stage of many febrile disorders. Rigors, though occasionally absent, constitute one of the most striking phenomena of pyæmia. They vary in number and frequency, sometimes occurring at short and irregular intervals, sometimes assuming a quotidian character, and generally ceasing after the first two or three days. Their duration ranges from a few minutes up to half an hour. The temperature of pyæmia has a good deal of resemblance to that of ague; the rigors are always attended with a rapid rise, which is followed by an almost equally

rapid fall. During, or after, the first rigor, the temperature may reach  $104^{\circ}$ ,  $105^{\circ}$ , or even  $107^{\circ}$ , or more, and the subsequent fall carries it down probably to a little above the normal, occasionally even below it. Subsequently, according to circumstances, the temperature may present a succession of similar elevations and depressions, or maintain a nearly uniform level. Death may be preceded by a normal, low, or even very high temperature. The skin, which is often harsh and dry, perspires profusely after the rigors, and copious perspirations recur from time to time during the progress of the malady, and attend its last stage.

The respiratory acts, as the disease advances, become frequent, independently of the presence of pulmonary complication, and not uncommonly reach 40, 50, or 60 in the minute; and the breath is said to acquire a peculiar sweet odour. The pleuritic exudation, the pulmonary lesions, and the excessive formation of bronchial mucus aggravate the symptoms due to the respiratory organs; and induce dyspnœa, cough with various forms of expectoration, pleuritic stitches, and friction, crepitation, rhonchus, or other auscultatory phenomena.

The feebleness of the pyæmic pulse is remarkable. It is generally rapid from the beginning, or, if not rapid, variable, so that the slightest exertion of body or mind raises it 20, 30, or even 40 beats in the minute. As the disease advances, it frequently rises to 140 or 160 in the minute, and may even reach 200; it then tends to become irregular and almost imperceptible. Pericardial friction or other signs of cardiac implication may of course arise.

Abdominal pain and tenderness may be caused by the presence of hepatic or splenic congestion or inflammation, or of circumscribed peritonitis in connection therewith. The jaundice, which is so common in pyæmia, appears to be quite independent of the presence of pyæmic deposits and abscesses in the liver. Frerichs remarks that, 'to all appearance the jaundice is here the result of an impaired consumption of bile in the blood, arising from an abnormal condition of the metamorphic processes which go on in that fluid.'

Urea is largely increased, and often the urine contains a small quantity of albumen.

Arthritic, periosteal, and other superficial abscesses are far more common in the chronic than in the acute form of pyæmia. Their formation is mostly indicated by the usual symptoms which attend such inflammation. Sometimes, however, they come on rapidly and with little or no pain.

The nervous symptoms are much like those of typhus and some other specific fevers. They vary, but comprise in the first instance either restlessness or apathy and drowsiness, and later on delirium, which may be violent, but is generally muttering, and often passes into coma. Muscular debility is always well marked from the beginning, and soon becomes extreme. There are often tremors or subsultus, and sooner or later loss of control over the bladder and rectum.

The time at which pyæmia arises in relation to the morbid condition on which it supervenes varies. In accident and operation cases, and in those of carbuncle and erysipelas, it may come on at any moment from the commencement of suppuration down to the period of complete recovery. In cases of acute suppuration connected with bone, and acute necrosis, pyæmic symptoms are sometimes present almost from the first. In puerperal women pyæmia usually manifests itself between the third and the tenth or twelfth day after labour.

The prognosis of pyæmia is exceedingly unfavourable. There is little doubt that recovery occasionally takes place; at the same time it rarely happens that this event ensues in cases which, from the severity of their symptoms, are distinctly recognised as pyæmic during life. The cases of recovery are usually those in which the symptoms from the beginning are mild, and which would probably not be recognised as pyæmic but for the fact of their occurrence during the endemic prevalence of the disease in the wards, say, of a lying-in hospital.

There is generally not much difficulty in the diagnosis of pyæmia when it arises after surgical injuries or parturition. There is much more difficulty when it occurs in patients who are already prostrated by acute inflammatory affections, such as carbuncle or erysipelas, the symptoms due to which are not unlike those of pyæmia itself. And it is particularly apt to be misunderstood when it arises out of some deep-seated suppuration. The diseases for which it may be especially mistaken, and for which it has been mistaken over and over again, are typhus and enteric fevers, internal acute inflammations (especially of the lungs), urethral and bladder affections in which the kidneys have become involved, glanders and acute rheumatism. It is a good rule when a case comes under treatment in which typhoid symptoms with great prostration have developed themselves very rapidly, and in which from the absence of any specific symptom the physician hesitates to form a definite diagnosis, to examine the limbs and surface of the body carefully. It has more than once happened to us in such cases to recognise, by the increased bulk of a thigh or arm, the source of the symptoms in the existence of a subperiosteal abscess.

It is difficult, if not impossible, to distinguish clinically between the different forms of septicæmia on the one hand, and true pyæmia on the other. The symptoms are, in the main, alike in both cases; but in simple septicæmia there is necessarily absence of symptoms referrible to the secondary inflammatory lesions characteristic of pyæmia. It is well to bear in mind, however, that constitutional symptoms suggestive of pyæmia, coming on suddenly in the course of unhealthy ulceration, may be due simply to septic poisoning, and may subside as the ulcerated surface cleans. In these cases there may or may not be an initial rigor; but among the more striking phenomena are, mental apathy or delirium, vomiting and diarrhœa, dryness of tongue, feebleness and rapidity of pulse, perspirations, extreme muscular debility and rise of temperature. And further, it may be noted, that cases (such as are met with in

puerperal women) resembling pyæmia in their onset and main symptoms, proving rapidly fatal, and presenting post mortem no secondary lesions, are probably to be regarded as cases of true and uncomplicated septic infection.

*Treatment.*—Very little, unfortunately, can be done medically for a case of pyæmia. We cannot cure the complaint; we cannot arrest it; we cannot, so far as we know, eliminate from the system any poisonous matter to which it may be supposed to be due. Quinine has been exhibited with the object both of checking the periodic rigors and of reducing excessive temperature; cold baths also have been used with the latter object; hot baths have been employed to promote perspiration, purgatives to aid elimination from the bowels, antiseptics of various kinds to obviate the supposed putrefactive tendency of the disease. But all to little purpose. Our main aim must be, on the one hand, to support the patient's strength by regulated and suitable diet and the moderate employment of stimulants, in aid of which vegetable tonics in combination with the mineral acids are often useful; on the other hand to relieve, as far as may be, all distressing symptoms and injurious complications, for which various purposes no drug is so generally useful as opium or morphia. Where symptoms suggestive of pyæmia show themselves, it is of the utmost importance to attend to the condition of the part which is its supposed source; not so much, however, for the purpose of arresting pyæmia in actual progress as of preventing the occurrence of what may perhaps only threaten. Unhealthy wounds should be freely laid open, deep-seated abscesses freely incised, and, if deemed necessary, antiseptic or caustic injections or applications freely employed.

In surgical and obstetrical practice, especially that of hospitals, the question of the prevention of the spread of pyæmia is one of the highest interest. No doubt pyæmia very frequently occurs sporadically among both surgical and obstetrical patients. But, whenever either pyæmia or erysipelas, no matter how it has originated, appears among groups of such patients, we know that there is a remarkable tendency for it to spread. To obviate this tendency, extreme cleanliness, ample ventilation, scrupulous nicety with respect to the treatment and dressing of raw surfaces, and especially the utmost care not to allow infection to be conveyed from one to another by the fingers of the medical and other attendants, are essential. The extreme value of Lister's antiseptic method of operating and treating raw surfaces is now almost universally acknowledged.

---

#### XXIV. LEPROSY (*Elephantiasis Græcorum*)

*Definition.*—A specific disease, endemic in many parts of the world, characterised by the slow development of nodular growths in connection with the skin, mucous membranes, and nerves, and (in the last case) by the supervention of anæsthesia, paralysis, and a tendency to ulcerative destruction and gangrene.

*Causation and history.*—Leprosy has doubtless been largely confounded with other maladies, such as elephantiasis Arabum, syphilis, and various affections of the skin, but has yet been recognised from the earliest times, has been described under various names, and has been regarded with perhaps more general superstitious awe and dread than any other known disease. It was probably not uncommon throughout Europe during the first two-thirds of the Christian era; but it underwent a marvellous increase during the twelfth and thirteenth centuries. An epidemic wave seems then to have spread slowly from the south-east to the north-west; and it was assumed, indeed (though probably erroneously), that at that time it was imported into Europe by the returning Crusaders. The disease prevailed generally with great severity during the succeeding two or three hundred years, then began to subside, and had finally disappeared from the greater part of Europe by the end of the seventeenth century. This subsidence of leprosy was closely related in time with the asserted introduction of syphilis; and hence it has been maintained (in spite of the clearest proof to the contrary) that these diseases are co-related, and their manifestations mere modified results of the operation of the same virus. But although the greater part of Europe became thus free at the date above assigned, the disease lingered in the Faroe Isles up to the commencement of the present century, and still prevails in certain parts of Italy, Greece, Spain, Portugal, and Russia, and with especial severity in Norway, Sweden, and Finland. At the present day, however, leprosy is mainly a disease of tropical and sub-tropical climates, and among these its chosen habitats are, perhaps, Central and Southern Africa, India and China, the West Indies, and South America. The etiology of leprosy has been largely discussed. Temperature, climate, soil, race, habits, food, have all been regarded as predisposing, if not exciting, causes. That temperature has no obvious specific influence is manifest from the fact that the disease prevails alike in Norway and in India. That soil and climate are equally inoperative is shown by the fact that it occurs both on marshy soils and at high elevations, both on the sea-coast and in inland regions, both in continents and in islands, and in nearly all latitudes. At the same time it is worthy of note that a large number of the localities which it specially affects are low-lying and marshy, and on the sea-coast or banks of rivers. That race and habits are not specific causes is clear from the prevalence of the disease amongst races of the most diverse kinds, and amongst persons of the most opposite habits. Yet it may probably be admitted, and has been asserted, that of several races living associated together and under many similar conditions, some are more prone to leprosy than others; and also that the disease is on the whole more common among the poor and filthy than among the well-to-do and cleanly. As regards the influence of diet, it may be pointed out that it has been attributed to the use of decomposing fish; but, unfortunately for this theory, the disease is met with where not only fish is never eaten, but where the diet is mainly vegetable. It follows necessarily that if the cause of leprosy

reside in any of the conditions which have been enumerated, that condition has at all events as yet escaped recognition. Formerly the disease was regarded as highly contagious, and consequently all communication between the sick and the healthy was rigorously interdicted. At the present day, however, its contagiousness is almost universally denied by scientific medical men; and it is beyond doubt that the attendants on the sick apparently fail to take it, that children live habitually in the same house with leprous members of their family without becoming affected, and that even sexual cohabitation may go on for years without the disease being transmitted from the diseased person to the healthy one. On the other hand, it seems to be clearly established that the disease is to a considerable extent hereditary—hereditary, that is to say, in the same sense as tubercle and carcinoma are hereditary, but not in the sense in which syphilis is hereditary. In other words, it appears, not that children are ever born with leprosy, but that the children of leprous parents are more likely to become affected than are the children of healthy parents—a fact which probably explains the supposed influence of race. It must indeed be admitted that the causes of leprosy, of its generally endemic character, and of its occasional epidemic prevalence, are alike unknown. That the disease has a specific character is quite clear; and that the tendency to it (if not the disease itself) is transmissible from parent to child, is equally clear. But whether it belongs to that class of diseases which is represented by tubercle and carcinoma, or whether, like ague and goître, it is the result of some obscure telluric condition, or whether, like scurvy and ergotism, it is due to some default or error of diet as yet unrecognised, or whether, like cholera, enteric fever, or syphilis, it is imparted in some special way by the sick to the healthy, are matters in regard to which we have no accurate knowledge. Certain recent statements in respect to the introduction of leprosy into the Sandwich Islands and into Australia, and its subsequent spread in those countries (assuming them to be correct), go far to establish its communicability. Dr. Liveing concludes that, if not contagious in the ordinary sense of the word, it is capable of propagation by the imbibition of the excreta of lepers.

The suspicion that leprosy is directly or indirectly contagious derives some confirmation from the discovery of bacilli, apparently specific, in persons suffering from the disease. They were first recognised by Hansen, in 1874. Since that time the fact of their presence has been confirmed by numerous observers. The bacillus lepræ (which presents an almost exact resemblance to the bacillus of tubercle, but is more readily stainable) is found in the tissues of leprous patients, but mainly and very abundantly in the specific leprous growths.

*Symptoms and progress.*—Leprosy is a disease of both sexes and all ages, but commences most commonly in early adult life. It is usually preceded by premonitory symptoms which continue for weeks, months, or years, before the specific signs of the disease manifest themselves. These consist in the first instance in lassitude and depression, attended with

more or less febrile disturbance, rigors, nausea, and loss of appetite. After a time livid blotches make their appearance here and there on the surface of the skin, remain out for a few days or weeks, and then subside, to be followed at irregular intervals by other similar outbreaks. They are tender, elevated discs, or rings, or more or less irregular patches, varying perhaps from half an inch to two or three inches in diameter. In the course of time the blotches become more persistent, and their subsidence is followed either by brownish pigmentary stains, or by an unnatural whiteness and opacity of the skin, associated with more or less contraction and depression. The central area of a patch not unfrequently assumes one or other of these conditions, while its periphery is still extending in the form of an elevated livid ring. During the earlier of these stages the affection has often some resemblance to psoriasis, lupus, or acne rosacea, and is sometimes termed *macular leprosy*; during the later of them the condition of skin is sometimes designated *morphæa nigra* or *alba*, according as the cicatricial area is pigmented or colourless.

The specific phenomena of leprosy now begin to develop themselves, and these vary according as the skin and mucous membranes on the one hand, or the nerves on the other, are principally affected. Many cases no doubt occur in which all of these tissues are implicated simultaneously or in succession. But in a large number the specific morbid processes are almost accurately limited to one or other tissue; and the disease hence assumes two distinct and easily recognised types. They are known as *tubercular* and *anæsthetic leprosy* respectively.

In *tubercular leprosy*, which is relatively most common in temperate climates, nodular elevations slowly develop themselves in the substance of the cutis, and mainly on the site of the macular eruption. These are attached by broad bases, become more and more prominent and sometimes pedunculated, and not unfrequently coalesce with one another so as to form irregular nodulated masses. They vary at length individually from perhaps the size of a hazel-nut to that of a walnut. They are for the most part hard and resistant, of a dusky reddish or brownish hue, smooth and sometimes polished on the surface, and often, like those of lupus, present a certain degree of translucency. They are attended with little inherent pain or uneasiness, but are more or less tender, and are remarkable for their permanence and the little tendency they manifest to undergo degeneration or ulceration. Nevertheless they do occasionally, after a long time, become the seat of some partial fatty change, grow softer and almost fluctuating, and acquire a dirty yellowish hue; and not unfrequently also, when irritated by exposure, filth or injury, they become excoriated or ulcerated, or covered with thin scabs, and exude a serous or ichorous fluid. The growth of the tumours is attended with atrophy of the cutaneous glands and of the hair. The latter first becomes thin and dry and loses its colour, and then disappears entirely. The loss of hair, however, is not, as in syphilis, general, but simply limited to the situations in which there is obvious disease. The tubercles of leprosy occur mainly on those surfaces which are most exposed to the air, namely, the face,

hands, and feet, but they are common also on the extensor aspects of the limbs. On the face they chiefly affect the eyebrows and eyelids, the nose and lips, and the lobes of the ears. The nodulated thickening of the eyebrows and adjacent parts of the forehead gives a peculiar morose character to the expression; and the thickening of the nose and lips with the associated bronzing of the parts imparts to the European the appearance of the mulatto. When the face is thus affected the term *leontiasis* is sometimes applied to the disease. In the hands and feet the back or dorsum is chiefly involved. In addition to the cutaneous growths which have just been described, nodules of the same kind appear in the subcutaneous tissue. The morbid process is limited to the skin and subjacent tissues for a longer or shorter time; but at length certain of the mucous membranes become implicated, especially those of the nose, mouth, and larynx. The affection here is of the same kind as that in the skin; it consists in the formation of nodules, which increase in size, run together, and sometimes form flattened elevations. The growths, however, are softer, more readily ulcerate, and on healing leave deep and dense cicatrices. In the progress of the disease the cartilages of the nose not unfrequently become exposed, the tongue large, nodulated, and seamed with cicatrices, and the different parts of the larynx thickened and stiff, and its channel contracted. In association with the affection of the larynx a peculiar cough and hoarseness of voice become developed which are very characteristic of the disease. According to Danielsen and Boeck the trachea and bronchial tubes may undergo the same changes as the larynx. The conjunctivæ are apt to be similarly affected, and inflammation, suppuration, and perforation of the corneæ to ensue.

In *anæsthetic leprosy*, which is specially common in hot climates, it not unfrequently happens that no tubercles are ever developed. And the cutaneous affection may be either that which has been described as among the prodromal phenomena of leprosy, or so slight that attention is first called to it by some impairment or change of sensibility. There may even be no structural change whatever. We will first consider the nervous phenomena, and afterwards the local processes going on in the skin and subjacent parts. In the first instance there may be a combination of hyperæsthesia and anæsthesia, some parts being numb or insensible while others burn or tingle and are excessively tender, and not unfrequently areas of numbness are surrounded by rings of increased sensibility; these conditions, moreover, replace one another, so that parts which were hyperæsthetic become anæsthetic; and, further, they may occupy numerous scattered spots or pervade separately or in combination extensive tracts of skin. They are often connected, though by no means necessarily so, with the cutaneous maculæ. The affection of the sensory nerves is generally associated with affection of the motor nerves, and indeed the latter (although it seems to come on later) occasionally preponderates. Thus there are often tremblings and jerkings of the limbs; but especially there soon supervenes muscular paralysis. The anæsthetic and paralysed regions gradually shrink, the fat, the muscles, and even the bones waste,

and the skin contracts over them, becoming white or pigmented, and assuming a cicatricial character. The parts which are generally first affected, and which suffer most severely, are the hands and forearms, feet and legs: in the upper extremity mainly the districts supplied by the ulnar nerve, and in the lower extremity the regions correspondingly situated on the outer side of the leg and foot. It will be recollected that the ulnar nerve, besides giving sensory branches to the inner side of the lower part of the arm, to the inner side of the hand, and to the ring and little fingers, supplies motor nerves to the flexor carpi ulnaris, the inner half of the flexor profundus, the muscles of the ball of the little finger, the interossei, the adductor muscles of the thumb, and the palmaris brevis. And the consequence of their wasting and loss of function is that the palm becomes flattened, the thumb separated from the other fingers, and these powerfully extended at their first joints, and flexed at their second and third joints: conditions which impart to the hand the well-known claw-like form which always results from paralysis of the ulnar nerve. Bullæ not unfrequently form and burst, sometimes healing quickly and well, at other times leading to obstinate ulcers, which leave hard depressed cicatrices behind. After a time gangrene occurs in the affected parts, more especially the hands and feet. This sometimes begins from the surface, and gradually deepens, until the bones are exposed; sometimes begins among the deeper tissues, and involves the skin secondarily. It often ends in the separation of the bones, in the loss of fingers or toes, or even of a hand or foot. It is remarkable, however, how rapidly and perfectly wounds thus made heal up.

The duration of leprosy is very uncertain: that of the anæsthetic variety is, on the average, sixteen or seventeen years, that of the tuberculated form eight or nine. Death is due partly to gradual impairment of nutrition, but mainly to the supervention of complications, especially phthisis, dysentery, and kidney affections.

*Morbid anatomy and pathology.*—The morbid process on which the chief phenomena of leprosy depend consists in the infiltration of the affected tissues with innumerable small cells containing comparatively large nuclei. These, in accordance with Virchow's views, are probably due to proliferation of the connective-tissue corpuscles; and collectively form more or less extensive masses of new growth which are almost identical microscopically with granulation-tissue and with the tissue of syphilitic gummata, and lupus. The leprosy growth differs, however, from the latter two especially by its permanence and comparatively little tendency to undergo degenerative changes. The new growths present, at all events during their earlier progress, a greyish, yellowish, or brownish tint, are firm, translucent, and homogeneous in texture, and contain few blood-vessels and little blood.

In tubercular leprosy the tumours commence in the skin around the hair follicles and glands, which in their progress they gradually compress and destroy, together with the majority of the other textures which they involve; the epidermis, however, remains for the most part normal, and

the muscles of the hairs, in the beginning at all events, become hypertrophied. The tubercles do not usually admit of being enucleated, but are connected by processes with the subcutaneous connective tissue. Their formation beneath the skin and in connection with the mucous membranes essentially accords with the above description. Both in the macular stage and in the anæsthetic form, the cutis, however slightly it may appear to be affected, is the seat of specific proliferation.

In anæsthetic leprosy the nerves are always implicated: the smaller branches being mainly involved, and of the nerve-trunks those portions which are most superficial and most obnoxious to injury. They swell to several times their normal bulk, sometimes uniformly, but more frequently irregularly, so as to present something of a beaded character. They become at the same time firm, greyish, and translucent. The change is due to a proliferation of the cells of the connective tissue of the nerve-bundles (mainly of that which separates the individual nerves from one another, and of that which bounds and isolates their different strands), and exactly resembles what occurs in the skin and mucous membranes. At first the essential elements of the nerves suffer but little from the adventitious growth which surrounds them; eventually, however, they undergo degeneration.

Dr. Vandyke Carter<sup>1</sup> shows that, in anæsthetic leprosy, the affected muscles become converted into fibrous tissue; and that the bones especially of the hands and feet waste; that the carpal and tarsal bones suffer thus to some extent, but that the metacarpal, metatarsal, and phalangeal bones are chiefly affected, and in an increasing order from the first of these to the last phalanges; that their shafts become attenuated, and their distal extremities disappear. He shows also that these conditions involve mainly the fourth and fifth fingers and the corresponding toes, and that here the last phalanx not unfrequently disappears wholly, the skin and nail then shrinking on to the top of the second phalanx.

We have already adverted to the statement of Danielssen and Boeck that leprosy patients are liable to the development of specific tubercles throughout the bronchial tubes; they describe them also as occurring in the substance of the lungs, liver, and other organs. These statements have not, however, been fully verified by subsequent observers. In all forms of leprosy the lymphatic glands become largely hypertrophied, especially those in immediate connection with diseased districts. The glands which chiefly suffer are those of the groin, neck, and submaxillary region. Distinct leprosy infiltration, with degeneration, of the testicles is recorded by Virchow.

The ulceration, gangrene, and other inflammatory processes, which are so common in the course of leprosy, seem to be due, not so much to any special tendency which leprosy formations have to pass into such conditions, as to what may be regarded as accidental circumstances. Thus in the case of tubercular leprosy, ulceration seems to result from the

<sup>1</sup> On Leprosy and Elephantiasis, 1874.

effects of exposure, cold, dirt, and other sources of irritation; and, in the case of anæsthetic leprosy, the ulceration and gangrene are probably mainly dependent on the irritative implication of the nerves.

*Treatment.*—By common consent leprosy is an incurable disease; nor does it admit of alleviation or arrest by medicinal treatment; but it is doubtless well, when the case allows of it, to remove the patient from a locality in which the disease is endemic, to protect his surface as far as possible from injurious influences of all kinds, and to maintain his strength by appropriate food and various tonic adjuvants.

---

## XXV. AGUE (*Intermittent and Remittent Fever*)

*Definition.*—A specific non-contagious fever, produced by malaria; characterised by enlargement of the spleen, and recurring attacks of fever, attended each with a cold, a hot, and a sweating stage; and having an indefinite duration, and a tendency to recur which may last for many years or during the whole of life.

*Causation and history.*—Ague is undoubtedly not contagious. It is not communicable from man to man, nor does it spread from a centre, successively invading town after town and country after country. It is strictly an endemic affection, belonging to certain districts and induced in them by some poisonous influence which pervades them. Ague-districts are scattered more or less irregularly over the whole non-aqueous surface of the globe, excepting apparently that of the frigid zone. And the virulence of the poison which they yield increases for the most part as they approach the equator. They generally present certain common features: they are tracts of low-lying marshy ground, often situated upon rivers or lakes or in the vicinity of the sea, often presenting a luxuriant vegetation, and always a porous soil which is commonly composed to a large extent of decaying vegetable matter. But, however fever-stricken such places may be, the malaria which they breed is evolved at certain seasons only. In our own country, and probably in all temperate climates, the dangerous periods are spring and autumn, especially autumn; in the tropics, the season of heat and drought which follows upon the periodical rains; and in all cases, it would seem that the poison is produced only or with special intensity, not when the marshy ground is thoroughly soaked, but when, after it has been thus soaked, the surface to a little depth has undergone a rapid process of drying. What, it may be asked, is the condition common to all the variously situated aguish regions which causes ague? Is it high temperature? Clearly not; for many of the hottest regions of the earth are completely blameless. Is it the presence of water? The answer must be No; for, if aqueous vapour could cause ague, all who frequent the sea, or live in the vicinity of rivers, should contract ague; and especially, aguish districts should be most dangerous at those very times when they are now most free. Is it the presence of decaying

vegetable matter? Again the answer must be No. Decaying vegetable matter exists abundantly in places where ague never occurs; and moreover, as Sir Thomas Watson remarks, if such matter could cause ague, Londoners ought at least to be occasionally infected by the contents of their dust-bins and by the neighbourhood of Covent Garden Market. But the specific influence of decaying vegetables in the causation of ague is disproved by the fact that ague prevails in certain places where no such matter exists. 'In August, 1794, after a very hot and dry summer, our army in Holland encamped at Rosendaal and Oosterhout. The soil in both places was a level plain of sand, with a perfectly dry surface, where no vegetation existed, or *could* exist, save stunted heath plants. It was universally percolated to within a few inches of the surface with water, which, so far from being putrid, was perfectly potable. Here fevers of the intermittent and remittent type appeared among the troops in great abundance.' (Watson.) Again, the soil of Hong Kong consists of disintegrated granite, containing, according to Parkes, less than 2 per cent. of organic matter; yet ague, which had not previously prevailed, became rife and fatal at a time when the soil was being extensively excavated for building purposes. The last quotation illustrates another point of considerable importance in relation to the causation of ague, namely, the influence in this respect of upturning of the soil—of soil, at any rate, which has long been untouched. The malarious affections which prevailed in the armies before Sebastopol are referred by Trousseau to this cause; and he also points out that in Paris, where ague is almost unknown, epidemics of limited duration have on several occasions been distinctly traced to the formation of extensive excavations.

It would seem, therefore, that neither heat, water, nor decomposing organic matter is alone capable of evolving the malarious poison; but that for its production there must be a certain porous character of soil, a certain degree of saturation of this soil with water (the surface having recently undergone desiccation), and a certain elevation of temperature. Nothing is more certain than that anguish districts may be rendered healthy by drainage. In London, much of which is built on land which was formerly marshy, and where ague was once largely prevalent, the disease is now rarely if ever met with, unless it be imported.

The malarious poison appears to be manufactured in the soil of the malarious district, and to be exhaled from the surface in company with the moisture which rises from it, and by night far more abundantly than by day. It forms over the infective area a kind of invisible mist, which is denser and more potent in proportion to its proximity to the ground, and which extends to no great height above it. Indeed, it is well known that the ground-floors of houses in anguish districts are more dangerous to sleep in than are the upper stories; and that the miasm rarely ascends to any great height the sides of mountains which adjoin such districts. Parkes considers that the upper limit in temperate climates is 500 feet, in tropical climates from 1,000 to 1,500 feet. As might be supposed, the miasm may be carried by the wind and atmospheric currents beyond the

limits of the area in which it is produced ; and thus, under certain circumstances, places which are miles away, and in all other respects healthy, not unfrequently become affected. It seems, however, that the miasm is absorbed in its passage across water, so that the intervention of a river three-quarters of a mile or a mile broad, or of a similar breadth of sea, gives perfect safety. Even a belt of trees, acting probably as a kind of filter, often forms an efficient barrier. For the latter reason it is dangerous to sleep under trees in malarious places. It is also dangerous, according to some, to drink the water, however pure it may seem to be, which is furnished by the soil of such localities.

What, then, is this miasm ? Is it a gas, is it some decomposing organic substance, is it a living thing ? No absolute proof has yet been adduced of the truth of either of these alternatives. There is, however, much, both in the behaviour of the miasm and in its effects on the human body, to indicate a generic relationship with the contagia of infectious fevers, and to render it probable that the last of the alternatives above expressed is entitled to acceptance. Salisbury, of Cleveland, indeed, believed that he had discovered the specific cause in the sporules of certain algæ, species of palmellæ ; and more recently (1879) Klebs and Tommasi-Crudeli<sup>1</sup> state, from investigations conducted at Rome, that they are enabled to obtain from the soil and air of marshy districts, and to cultivate, a microphyte having a close resemblance to the bacillus anthracis, and termed by them the ‘bacillus malarie,’ by the inoculation of which they can produce ague in rabbits. Further, it is stated that the bacilli may always be found post mortem in the spleen, marrow, and blood of men and other animals dying during an attack of ague ; and that they are present in abundance in the blood at the commencement of the febrile paroxysm, but disappear as it attains its height.

There are certain facts in reference to the causation of ague, besides those which have been considered, to which attention should be drawn. It seems to be well ascertained that the denizens of malarious districts become, in a greater or less degree, acclimatised, and hence less readily contract ague than persons newly arrived. It is remarkable how little the negroes suffer in districts which are fatal to Europeans. Another well-ascertained fact is that persons suffering from fatigue or privation are much more liable to take the disease than those who are well fed, strong, and in robust health. Again, contrary to all we know of most other fevers, especially of the exanthemata, one attack of ague, so far from being protective, renders its subject more than ever liable to be again attacked with it on exposure to its exciting cause.

*Symptoms and Progress.*—The period of latency of miasmatic affections varies within wide limits. Authentic cases are recorded in which persons who have been exposed to the paludal poison have manifested the first symptoms of fever within the ensuing four-and-twenty hours. On the other hand, it not unfrequently happens that persons who have been

<sup>1</sup> ‘Archiv für experimentelle Pathologie,’ July and October, 1879.

residing in aguish districts at the time of year when ague chiefly prevails have their first attack of ague many months after they have removed thence to some perfectly salubrious locality. Thus we frequently meet with persons, residing in healthy parts of London, who are attacked during the spring or summer with symptoms of ague, the poison of which was taken into the system during the previous autumn, in Essex or Kent, and had lain dormant during the whole of the intermediate period.

Ague presents itself clinically in two well-marked extreme forms, which, however, pass one into the other by insensible gradations. The first of these is the intermittent fever, which is especially common in temperate climates, and comparatively mild; the second is the remittent fever, which occurs chiefly in the tropics, and is of great severity and danger. We will describe first the phenomena of intermittent, and then those of remittent fever.

A. *Intermittent fever* is characterised by the occurrence of febrile attacks of some hours' duration, separated from one another by periods of apparently, or, at all events, comparatively, good health. The patient is attacked suddenly, or after having complained for some indefinite time of lassitude, headache, and general malaise, with a sense of chilliness, and weariness, headache, muscular pains, and epigastric discomfort. The chilliness rapidly increases until the patient feels and looks as if he were suffering from intense cold. He begins to shiver—the sensation of shivering commencing in the back and extending thence to the rest of the body. The shivering is speedily converted into a severe rigor, attended with violent chattering of the teeth and convulsive tremblings of the trunk and limbs. At the same time the skin is dry, and assumes the papular condition known as 'goose's skin;' the face and the hands and feet acquire a dusky hue, the face also looking pinched, the hands and feet shrunken and wrinkled. Whilst this condition lasts the pulse is small, frequent, and often irregular; the respirations are quick and sighing; there is loss of appetite, thirst, and epigastric oppression, not unfrequently associated with sickness; the tongue is perhaps bluish, and slightly furred; headache and pains in the back and limbs are often present, and sometimes torpor or drowsiness; and the urine is pale, abundant, and passed frequently. The length of this, which is termed the *cold stage*, presents great variety. In some cases it is represented by a slight sensation of chilliness of a few minutes' duration only. It more commonly lasts from half an hour to one or two hours, and is occasionally prolonged to three or four hours, or even more. During the whole of this stage the temperature of the patient is above the normal, and rises rapidly. The elevation begins in fact before the patient himself recognises the commencement of his attack, and rises quickly and uniformly until towards the close of the stage; at which time, even though he be still trembling violently with the feeling of intense cold, the thermometer placed in his axilla probably marks  $105^{\circ}$ ,  $106^{\circ}$ , or even  $106.3^{\circ}$ .

After a time the cold stage subsides, and the next, the *hot stage*, commences. The rigors and aspect of chilliness gradually disappear—slight

flushes at first alternating with the diminishing rigors, and then by degrees replacing them. The patient begins to feel comfortably warm, and the shrunken and livid surface assumes the smoothness and hue of health. But gradually the feeling of heat gets intense; the patient looks excited and flushed; the skin feels dry, harsh, and pungently hot; the pulse becomes fuller, stronger, and soft, but maintains its frequency; the respirations get more rapid and deeper, and the thirst more severe; anorexia continues; the urine is still abundant, but of a darker colour and higher specific gravity; and the headache, which differs in character from that previously complained of, becomes extreme; mental confusion is not uncommon, and occasionally there is slight delirium. During this stage the temperature continues high; sometimes during the early part attaining a higher elevation than was reached during the cold stage, sometimes, on the other hand, falling somewhat below it. The hot stage lasts from one or two hours up to four or five, but is occasionally prolonged to eight or ten hours.

The hot stage is succeeded by the third or *sweating stage*. The approach of this is indicated by the supervention of a general feeling of comparative comfort; the intense heat of skin diminishes somewhat, and moisture appears on the face, and rapidly involves the whole surface of the body; soon the patient is bathed in profuse sweats; the temperature rapidly falls; the pulse becomes less frequent and softer; the respirations resume their normal rate; the headache disappears; the loss of appetite and the thirst abate; the urine gets scanty, but of variable colour, and deposits a sediment on cooling; and not unfrequently the patient falls into a gentle sleep. The duration of this stage is very various, but is generally shorter than either of the other two. On emerging from it, the patient may still be languid and listless, but on the whole appears to be restored to more or less perfect health.

The duration of the febrile paroxysms and that of their different stages present considerable variety. The whole paroxysm may be completed in an hour or two, or may be prolonged to eight or ten, or even twelve hours. The cold stage, as has been pointed out, may last from a few minutes to some hours, and not unfrequently the shorter cold stage is followed by the longer and more intense hot stage. Again, the hot stage, which is often of some hours' duration, is occasionally absent—the sweating stage in such cases following immediately upon the cold stage. And lastly, the sweating stage may be so slight as almost to escape notice, or may be protracted for many hours.

The period which intervenes between the cessation of one attack and the commencement of the attack next following is called the *intermission*. In it the patient seems not unfrequently to be in the best of health. Sometimes, however, he suffers from more or less malaise, the degree and character of which depend on various circumstances which need not be specially considered.

The period which elapses between the commencement of one attack and that of the attack which is next in sequence is termed the *interval*.

And it is mainly in accordance with the length of this interval that we determine the different varieties of ague. In one variety the interval is twenty-four hours, or thereabouts, and there is consequently a daily febrile paroxysm. This is termed *quotidian ague*. In another variety the interval is forty-eight hours, more or less, and the paroxysm occurs every other day. This should strictly be called 'secundan ague;' but those who framed its name chose to reckon the day of the first attack as one day, the day of freedom as another day, and the day of the next attack as the third day, and consequently attached to it the inaccurate but now well-known name of *tertian ague*. In another variety the febrile paroxysms occur every third day; and this, which should strictly be named tertian ague, has received the designation of *quartan ague*. In addition to these three principal varieties, others which are much rarer are occasionally met with. Thus, in some cases the fits recur every fourth, fifth, or even sixth day; and in some cases we have what are termed *double tertians* or *double quartans*. In the double tertian the patient has febrile paroxysms occurring every day; but, while those of the odd days correspond with one another, in time of commencement, duration, and probably also other features, those of the even days, though presenting a like agreement among themselves, differ markedly from those of the other series. In the double quartan the patient suffers, as it were, from two series of quartan attacks: the first series of similar paroxysms occurring, say, on the first, fourth, and seventh days; the second series occurring on the second, fifth, and eighth days.

In quotidian ague the febrile paroxysm usually commences earlier and lasts longer than in either of the other common varieties—often persisting for ten or twelve hours. In the tertian variety its duration is usually six or eight hours; in the quartan four or six. On the other hand, the cold stage is shortest in quotidian, longest in quartan ague. The interval, as has been pointed out, is rarely exactly twenty-four, forty-eight, or seventy-two hours; when it falls short of either of these periods each successive febrile attack commences earlier in the day than that which immediately preceded it, and is said to *anticipate*; when the interval is prolonged, the periodical paroxysms become later and later, and are said to *postpone*. In the former case the disease is generally becoming more severe; in the latter case there is usually a tendency towards improvement. Tertian ague, is, at any rate in Europe, more common than either of the other varieties; none of them, however, is rare, and they readily and not unfrequently pass into one another.

B. *Remittent fever* (the form of ague most common in tropical climates) is much more serious and dangerous to life than the intermittent forms of ague which have just been considered. Its distinguishing feature is that the febrile paroxysms, which come on once or twice a day, are not separated from one another by intermissions of complete apyrexia, but are rather to be regarded as exacerbations of an abiding febrile state. Further, the cold stage of each exacerbation is always of short duration, sometimes indicated by a few minutes only of shivering or chilliness, and sometimes

escaping recognition; the hot stage is much prolonged, lasting from six to twelve hours; and the sweating stage is imperfectly developed and merges into the period of remission from which it is undistinguishable. The attack of remittent fever is sometimes sudden; but is more commonly preceded by premonitory symptoms, such as chilliness, lassitude, loss of appetite, nausea, epigastric uneasiness, and pains in the head and limbs. The actual febrile paroxysm begins with a rigor or slight chilliness, to which the hot stage speedily succeeds, and after some hours ends in perspiration and the period of remission—the remission, like the hot stage, varying in length from two or three to twelve hours. The paroxysms usually increase in intensity day by day for a few days. The symptoms which the patient presents are for the most part like those which attend intermittent fever, but some of them are much more severe. The temperature attains no greater height, but it never falls during the remissions to the normal standard; there is no difference as regards the respirations and pulse, except perhaps that the latter with the progress of the disease tends to become quicker and weaker. Sickness is much more severe during the hot stage of remittent fever than in the corresponding period of intermittent fever, is often very distressing, and sometimes attended with hæmatemesis (black vomit); the tongue is drier, and occasionally there is slight jaundice; headache and pains in the limbs are more intense; confusion of intellect is more common, and drowsiness, delirium, and coma are not unfrequent. The patient often passes into a distinct typhoid condition, with dry brown tongue, sordes on teeth, muttering delirium, subsultus tendinum, and other symptoms of the kind.

Remittent fever presents at first sight an almost closer relationship, in the type of its fever, with enteric fever and hectic (which usually also are distinctly remittent), than with the varieties of intermittent fever. And indeed enteric fever and hectic were formerly, in many of their forms, termed remittent, and regarded as of malarious origin. It is certain, however, that the so-called remittent fevers of temperate climates have no affinity with ague. And, on the other hand, it is equally certain that there is no essential difference between the remittent and intermittent forms of ague. For not only do they arise from the operation of the same miasm, and present symptoms essentially alike, but their varieties shade into one another by insensible gradations, and they alternate with one another or replace one another in the same individual.

The effects of the ague-poison are not always in accordance with the above description. Thus there are described: some cases in which the paroxysm consists in a violent and prolonged cold stage only, during which the temperature is actually lowered (the patient suffering from extreme anxiety and intense thirst, and looking like a corpse), or in which, independently of any other peculiarity, he falls into a condition of exhaustion, and lies torpid, motionless, and as if asleep, for many hours; others, in which the sweating comes on early, is exceedingly profuse and of long duration, and during which the temperature falls rapidly, and the patient

lies in a condition of extreme collapse ; others, in which the patient presents coma or delirium, or has epileptiform or tetanoid convulsions coming on in the hot or cold stage, and continuing until the establishment of the sweating stage ; and again others, in which hemorrhage takes place from the nose, stomach, bowels, bladder, or into the substance of organs. Further, there are various neuroses which are distinctly forms of ague, the more important of them being neuralgic affections of one or other of the branches of the fifth pair. That involving the supra-orbital constitutes one form of the malady known as ' brow-ague.' These may be recognised as being malarious, partly by their periodic character, partly by their occasional supervention on a more or less distinct cold stage, partly by their occurrence in a malarious district, partly by the fact that the patient has already been the subject of ague.

There are one or two points in reference to the paroxysms of ague to which we have hitherto only very briefly alluded, but which are nevertheless of considerable importance. In intermittent fever, during the cold and hot stages the urine is usually secreted in considerable abundance, is pale and of low specific gravity, and the patient generally has very frequent desire to micturate. He passes an excess of urea, uric acid, and chloride of sodium, while phosphoric acid is diminished. During the sweating stage the urine becomes scanty and darker coloured, and the amount of the excreted solids, which was previously in excess, undergoes diminution. In the intermission urea and uric acid fall below the normal standard. In the remittent form of ague the same peculiarities exist, but are necessarily somewhat less marked. In both forms there is occasionally albuminuria or hæmaturia, with renal casts. The spleen is invariably enlarged during the paroxysms, becomes especially swollen during the cold stage, and may generally be easily recognised by palpation or percussion ; it then subsides, and during the intermission may return to its normal bulk. If, however, the ague persists, the splenic enlargement tends to become permanent.

The duration of ague presents great differences. An attack will probably always subside (unless death supervenes) after some indeterminate period ; especially it will subside if the patient be removed from the district in which he contracted it. But this subsidence is rarely final. In the great majority of cases the patient remains for months or years, or for his lifetime, liable to fresh attacks of ague, even if he never again ventures into a malarious district. The attacks then recur at irregular intervals, and are generally determined by some accidental circumstance, such as over-fatigue, an attack of catarrh or indigestion, or the occurrence of other ailments, whether mild or serious. In other words, the malarious poison becomes a portion of his being, and seems to tinge and qualify any morbid condition which happens to arise. Death from the ordinary intermittent fevers is rare ; but remittent fever, unless it be promptly treated, is a very fatal disease. The patient dies for the most part in the typhoid condition, and seldom (according to Maclean) before the eighth day.

If ague assumes a chronic form, and especially if the patient has been

long resident in an aguish climate, or has had periodical attacks for many years, organic changes take place in the liver and spleen, their functions become impaired or perverted, and chronic conditions of disease are sooner or later developed. Among the more important of these are various forms of cachexia and dropsy. In some cases the patients simply pass into a condition of debility and anæmia, on which general dropsy may supervene after a time; in some cases jaundice becomes associated with this anæmia, and from the same affection of the liver that causes this, ascites or hæmatemesis and melæna may eventually come on; in some cases, again, degeneration of blood-corpuscles takes place in the spleen, and their conversion there into brown or black pigment-granules, and the diffusion of this pigment thence throughout the system, give a peculiar dirty or bronzed hue to the complexion. Some degree of such discoloration, indeed, is often seen in persons who have had repeated attacks of ague.

In conclusion, it is not uncommon for the denizens of malarious regions to become the subjects of the visceral lesions and cachexiæ which supervene on ague without ever having experienced a distinct attack of ague—the malarious poison appearing to affect the system slowly and insidiously, and without even the warning which an occasional febrile paroxysm might afford.

*Morbid anatomy and pathology.*—The pathology of ague is very obscure; and morbid anatomy throws little light upon it. We know that a poison (probably living) is taken into the system, and that this remains incorporated with it for an indefinite period, giving rise at irregular intervals to more or less distinctly periodical attacks of well-marked fever, attended with rapid destruction of tissue, high temperature, and congestion of internal organs, more especially the spleen. But where the poison lurks, why it acts periodically, and on what organ or organs it acts chiefly, are matters concerning which we do not positively know anything. There is, however, good reason to believe, on the one hand, that it is not discharged from any surface, and on the other that (whether it acts directly or indirectly thereon) its main effects are wrought through the agency of the sympathetic system of nerves. It is scarcely probable that the enlargement of the spleen and associated changes in the liver, important though they be in many respects, are anything more than secondary phenomena. The only constant lesion discoverable after death is enlargement of the spleen. This organ becomes distended with blood, and often to many times its normal size; and if the patient die when the attack of ague is recent, it is found large and congested. The liver, too, is commonly to some extent engorged and increased in bulk. Congestion of the neighbouring parts of the alimentary canal has also been observed; and in hemorrhagic cases traces of hemorrhage at mucous surfaces and beneath the serous membranes may be discovered.

Enlargement and induration of the spleen and liver are among the common results of long-continued or repeated attacks of ague, or of long residence in malarious districts. Another change to which these organs are liable is a peculiar dark or slaty discoloration, due to disintegration

of blood-corpuscles and their conversion into pigment-granules. In the liver, this is generally referrible to the changes which occur in minute extravasations of blood into the capsule of Glisson and hepatic parenchyma; in the spleen, to similar changes going on in the blood which occupies the intermediate blood-passages. The pigment is apt to escape from the spleen, to enter the general circulation, and to become arrested in the capillaries of different organs, more especially the liver, brain, and kidneys, and thus not only causes them to be pigmented, but interferes with their nutrition, and induces various organic changes and functional disturbances.

*Treatment.*—What the prophylactic treatment of ague should be may be surmised from the foregoing account of the disease. First, when practicable, malarious districts should be thoroughly drained and cleared of underwood or jungle. Second, those who are compelled to remain in them should take ample precautions; should not go out in the evening, night, or early morning; should sleep in the higher rooms of the house they occupy; should not drink the water of the locality unless it be well filtered or boiled; especially should not expose themselves to the malarious influences when they are ill or fatigued; and on going out should, as Sir T. Watson suggests, wear charcoal respirators, and also regularly take such remedies as are efficacious in curing ague. And third, persons who are actually attacked with the disease should be removed to some healthy locality.

In treating ague medicinally we have to consider, first, the treatment of the paroxysms, and next that of the disease. It is reasonable to suppose that the ague-patient will experience some actual benefit if we assuage some of his discomforts, and hence that he will be benefited, during the cold stage, by the application of warmth, by packing, warm bottles, hot-air baths, or warm-water baths; during the hot stage by the maintenance of a cool atmosphere, by the use of light clothing, and by tepid or cold sponging; and, during both, by the administration of diluents. Little or nothing, in fact, is necessary beyond such simple measures. Other remedies, however, have been employed, and some reputedly with considerable success. Thus emetics have sometimes been given previous to the fit; and bleeding has been much lauded as a means of relief during the cold stage. The most valuable, however, of such special modes of treatment seems to be the exhibition of opium in largish doses (about thirty minims of the tincture) during the cold or hot stage.

It is of infinitely greater importance to attack the disease itself, and fortunately ague is one of those maladies for which we have almost unfailing remedies. Cinchona, indeed, its alkaloids, and arsenic are true specifics. There is no difference of opinion as to their efficacy; the only difference which can exist is as to the mode of their administration and the dose. Of the several cinchona alkaloids, quinine, in the form of the sulphate, is undoubtedly the most efficacious, and it is certainly much more convenient of administration than cinchona itself. There are two principal modes in which quinine is administered; by some physicians it is given in a single

large dose before each paroxysm is expected, by others in small doses at comparatively short intervals.

According to the former mode from twenty to thirty grains may be given for a dose to an adult. The time of its administration here, however, becomes important. By some it is thought best to give it just before the paroxysm, by others just after it and even during the sweating stage. The immediate object being prevention, it certainly seems most reasonable that the quinine should be given so long before the expected paroxysm as to allow of its being fully absorbed into the system before the occurrence of that event; and hence, of these two alternatives, the latter should be preferred. The plan, indeed, of giving the larger dose during the sweating stage can scarcely be improved upon either in the case of remittent or in that of quotidian ague. When, however, the paroxysms are separated by longer intervals, it is probably best either to divide the large dose into two smaller doses and to give them at intervals, or to give the full dose between six and twelve hours previous to the expected attack.

The other method, which is frequently pursued, is that of giving the quinine in smaller doses (three, four, or five grains) three or four times a day without reference to the times of occurrence of the paroxysms; and indeed it may be given freely even while a paroxysm is in progress. In some cases, owing to extreme irritability of the stomach, the quinine (in proportionately increased doses) must be given in the form of enema, or (in proportionately diminished doses) by subcutaneous injection. The time during which the administration of the remedy should be persisted in must necessarily vary with the case. It should be given for at least a week or two after all symptoms have disappeared; and should be at once renewed if a recurrence manifests itself. It is important, however, to observe that quinine (and the same is true of arsenic) does not, by continuous use, even for many months, necessarily eradicate the disease. Arsenic is equally efficacious with quinine in the treatment of ague, and indeed sometimes effects a cure when quinine has failed. The liquor arsenicalis may be given in doses of from five to ten minims three or four times a day.

It is generally considered advantageous to keep the bowels freely open, and indeed it is asserted that quinine and arsenic are occasionally inefficacious until a purgative has been administered. The complications and sequelæ of ague must of course be treated according to their nature; and the diet (in regard to which no special rules need be laid down) must be regulated by the condition and the tastes or desires of the patient.

## CHAP. II.—DISEASES OF THE SKIN

## I. INTRODUCTORY REMARKS

MORBID conditions of the skin are of great interest and importance, partly because they are very common, partly because they are in many cases a valuable aid to us in the determination of the nature of internal maladies, partly because their presence so largely affects, not only the health, but the comfort and happiness of those who suffer from them. Further, their position renders them comparatively easy of observation. For all these reasons they have been repeatedly investigated and described with extreme care, and have been distinguished with a degree of minuteness, and classified with an amount of ingenuity, which have been surpassed only in the distinction and classification of the members of the vegetable kingdom. The result has undoubtedly been largely to increase the range and exactness of our knowledge of skin diseases; but it may be questioned whether this result has not been to a great extent counterbalanced by the confusion which the introduction of a large number of names to designate trivial and often fanciful varieties of disease, and the pains taken to discriminate between conditions which are essentially identical, have tended to create.

But there is considerable excuse for minuteness of description and complexity of nomenclature of skin diseases, in the facts: that the skin is an extremely complicated organism, any one or all of the constituents of which may become the seat of almost any of the various morbid processes which have been considered in a former section of this work; that it differs greatly in character in different parts of the body, and is hence not equally liable everywhere to the same affections, or even to present identical appearances under the influence of the same disease; and, lastly, that it subserves various important functions, all of which are liable to modification or impairment in the presence of morbid processes.

*A. Classification and Definition of Terms*

We shall not classify skin diseases either according to the anatomical elements of the skin which are involved, as has been done by Erasmus Wilson; or according to their visible features, which constitutes the essence of Willan and Bateman's system; nor indeed shall we follow any

strictly logical scheme of classification. But we shall group them mainly in accordance with their mutual pathological affinities, not hesitating, however, to depart from this arrangement whenever it seems of practical utility, or convenient on any other grounds, to do so.

There are certain terms in common use in the description of skin diseases, which we proceed *in limine* to enumerate and explain; the more especially as there will thus be afforded a suitable opportunity for indicating the principles of Willan's artificial, but nevertheless very simple and useful, classification.

1. *Macula*.—By this term is generally meant a spot or patch of discoloration which does not fade on pressure, and in which, therefore, there is some obvious and more or less persistent deposit or change of texture. Freckles, moles, and port-wine marks are good examples of maculae. Under the same term may be included the circumscribed discolorations due to escape of blood into the tissue of the skin. But these are better known by special names. Extravasations, from about a line in diameter downwards, are (from their supposed resemblance to flea-bites) designated *petechiae*; larger effusions, such as may result from the coalescence of several petechiae, are called *vibices*; and those presenting the ordinary characters of bruises are known as *bruises* or *ecchymoses*. The term *stigma* is sometimes employed to indicate small patches or spots of vivid but readily effaceable redness, due merely to congestion, which appear suddenly, and often precede the development of vesicles, papules, or the pocks of vaccinia or small-pox; and the term *areola* or *halo* is applied to the ring, more or less broad, of redness which so often surrounds a definite spot of inflammation.

Willan's eighth order of skin diseases was that of the *macula*, and included, amongst other affections, freckles and the various forms of birth-mark.

2. *Exanthema* or *rash*.—These words are employed in reference, not to individual spots of disease, but to a more or less general eruption of spots or patches, which are inflammatory, and variously grouped, and, in the first instance at any rate, red, fading on pressure, and but little elevated above the general surface of the skin. The *exanthemata* formed the third of Willan's orders; and he included in it measles, scarlet fever, nettle-rash, roseola, purpura, erythema, and erysipelas. It is obvious, however, that he has here grouped together affections of the skin some of which have little in common with the others, and that he has excluded several which should really be regarded as exanthemata. Thus purpura is in no sense an exanthem, and erysipelas and erythema have no more right to that name than has acute eczema or impetigo. On the other hand, the eruptions of varicella and small-pox, and especially that of typhus, should certainly be regarded as exanthems. The term 'exanthem' should, indeed, be applied exclusively to the several eruptions which attend and characterise the infectious fevers.

3. *Papula* or *pimple*.—This is a small elevation at the surface of the skin, generally acuminate or pointed, but sometimes rounded, and rarely

exceeding the size of a large pin's head. It is very commonly congested, but by no means invariably so, and often attended with much itching. Papules are produced in various ways. In the condition known as 'goose's skin' there is a temporary production of them at the orifices of the hair-follicles in consequence of the contraction of the *arrectores pili*; and in the same situation papules often arise from the concentric accumulation of epidermis and sebaceous matter entangling young hairs. The pearly concretions so common in the sebaceous glands of the eyelids constitute another form of papule. Typical papules, however, originate either in enlargement of the normal papillæ of the skin, or in inflammatory exudation into the substance of the cutis.

The *papulæ* constituted Willan's first order, and comprised the various diseases known as *strophulus*, *lichen*, and *prurigo*.

4. *Tubercles* are solid elevations of the cutis, ranging roughly from the size of a hazel-nut to that of a papule, varying considerably in form and texture, and presenting more or less permanence. In form, they may be hemispherical, spheroidal and attached by comparatively narrow bases, conical, lobulated or warty; and not unfrequently neighbouring tubercles coalesce, and thus extensive surfaces may become irregularly thickened and lobulated. As to texture, it is sufficient, perhaps, to say that tubercles are sometimes cancerous, sometimes syphilitic, sometimes lupoid, sometimes due to inflammatory changes in sebaceous glands, sometimes simple warts.

The *tubercula* formed Willan's seventh order, and included boils, warts, molluscum, vitiligo, acne, sycosis, lupus, elephantiasis, and frambæsia.

A *wheel* may be regarded as a species of tubercle. Its special peculiarities are that it is of very transient duration, and that it forms a flat, generally circular, elevation, rarely exceeding a quarter or third of an inch in diameter. It sometimes presents a more or less vivid rosy tint, but is frequently pale, and in either case generally surrounded by a halo of congestion. It is usually attended with much itching. A wheal represents an early stage of inflammation; and the swelling which characterises it is due to effusion from the vessels of the part. Wheals may run together, and thus form bands or patches of considerable extent.

5. *Vesicles* are small accumulations of fluid, generally between the horny layer of the epidermis and the rete mucosum. Individually they vary, for the most part, from the size of a pin's head downwards; but they may be larger than that, and by mutual coalescence may form continuous tracts of considerable extent. They generally stand out prominently from the surface; but where the horny layer of the cuticle is thick, as on the palm and sole, they often present no elevation whatever, are imbedded, and can be recognised only by the peculiar greyish or bluish tint which they present. The amount of fluid relatively to the solid constituents of vesicles varies very much; and especially this is so if the vesicles are of inflammatory origin, inasmuch as the fluid effusion is then often associated with manifest thickening of the subjacent cutis and with overgrowth of the involved epidermis. Indeed, owing to this circum-

stance, the distinction between vesicles and certain forms of papules becomes purely arbitrary. Certain vesicles (*sulamina*) appear to be due simply to accumulation of sweat between the layers of the epidermis, and their contents are pellucid and acid. Generally, however, vesicles are the result of inflammation, spring up on a congested surface, and present contents which are alkaline, and, according to their age or other circumstances, transparent, milky, or tinged with the colouring matter of the blood.

The *vesiculæ* formed Willan's sixth order, and were made to embrace varicella, vaccinia, herpes, rupia, miliaria, eczema, and aphthæ.

6. *Bullæ*, or *blebs*, may be regarded as having the same relationship to vesicles that tubercles have to papules. The line of separation between vesicles and bullæ is quite artificial; generally speaking, however, a vesicle as large as a split-pea would be termed a bulla. Bullæ usually vary between this size and that of half a walnut. Occasionally they attain the bulk of an orange. But when thus large they are very often elongated and even sinuous as to their base, and their elevation is proportionately reduced. Their contents are identical with those of vesicles.

The *bullæ* were Willan's fourth order, and comprised pemphigus and pompholyx—affections now regarded as identical.

7. *Pustules* are accumulations of pus within or beneath the epidermis. They vary in size and form, and also in the degree in which they involve the deeper tissues of the skin. They sometimes commence as vesicles, the contents of which gradually suppurate; but very frequently they are purulent from the beginning. They are generally covered, as vesicles are, by the horny layer only; sometimes, however, by the whole thickness of the epidermis. The inflammation attending the formation of a pustule is much more intense than that which causes a vesicle or bulla, and consequently we find, as a rule, much greater congestion, thickening, and induration of the surrounding and subjacent parts in the former than in the latter case.

The *pustulæ* were Willan's fifth order, and included impetigo, porrigo, ecthyma, variola, and scabies.

8. *Furfura*, or *scurf*, is the name given to the thin bran-like scales, which separate from the surface of the skin on the subsidence of many of the exanthems, and which so commonly form upon the scalp. Scurf consists either of thin plates of epidermis or of a mixture of epidermis and sebaceous matter.

9. *Squamæ*, or *scales*, differ from scurf only in the fact that the plates of detached epidermis which constitute them are larger. They vary considerably, however, in size, thickness, colour, and consistence. Thus, they may be as much as a square inch in area, or even larger; they may be as thin as flakes of scurf or several lines in thickness—in the latter case being always more or less distinctly laminated; they may have the colour of the skin, or present various tints of yellow or brown; and they may be soft or hard, friable or tough. Some of these peculiarities depend on the amount of fluid which has been diffused amongst

the epidermic laminae during the process of their formation. The detachment of scurf or scales is called 'desquamation.'

Willan's second order was that of *squamæ*, and comprised lepra, psoriasis, pityriasis, and ichthyosis.

10. A *scab*, or *crust*, is the concretion formed upon a diseased surface by the drying up of the exudation which has taken place from it, and generally comprises therefore some of the normal elements of that surface, namely, epidermis and sebaceous matter. The exudation may be serum, pus, or blood, alone or combined in various proportions; and it is obvious that, according as these occur singly, or intermixed, or combined with sebum or epidermis, will the colour and other physical characteristics of the resulting scabs vary. Serum alone dries into thin yellowish or brown translucent flakes, pus alone into greenish scabs of some thickness, and blood into crusts which are black or nearly so. The admixture of sebaceous matter with serum or pus imparts to the resulting scab the colour and general aspect of gum or honey, and that with blood a brown or red tint. When many particles of epidermis are mixed with simple serous exudation, as in cases of acute eczema, the concreted product often assumes a powdery character and the colour of brimstone. Crusts vary in thickness, and are occasionally conical.

It is needless to discuss the meanings of the terms 'excoriation,' 'fissure,' 'ulcer,' 'cicatrix,' and many others which are in common use and generally understood.

#### *B. Tendency of Spots and Patches of Skin Disease to assume a Circular Form*

Before proceeding to the description of the different diseases, it may be worth while to point out that, while eruptions present great varieties of grouping or arrangement, the individual spots or patches almost invariably have at first a rounded shape, and that as they grow they maintain that shape, unless the form of the surface on which they are situated, or the direction of its grooves, or the union of neighbouring patches with one another, interferes with their regular development. Thus a vesicle, bleb, pustule, papule, or tubercle is almost invariably circular in the first instance; so is a patch of erythema, lepra, or pityriasis: and so also are the vegetable parasitic affections. In many cases, moreover, there is a tendency for the central part of the inflamed patch to resolve whilst its periphery is extending; and then it not unfrequently happens that the enlarging ring breaks up into fragments, and that some of these form the starting-points of other circles or segments of circles. It is easy to understand from this statement how the sinuous, serpentine, and other curious forms which skin diseases frequently assume are produced.

## II. ERYSIPELAS

*Definition.*—An acute inflammation of the skin, originating for the most part in the neighbourhood of wounds or sores, attended with much redness and infiltration and severe febrile disturbance, and characterised by a marked tendency to spread over the surface, and (especially in the presence of wounds) to become contagious.

*Causation.*—Erysipelas is either traumatic or idiopathic: that is, it either occurs in connection with wounds, or arises apparently spontaneously on surfaces which were previously sound. The former variety may be developed, therefore, on any part of the body on which wounds have been inflicted, or wherever conditions equivalent to wounds exist, as, for example, in connection with other forms of cutaneous disease, and about the umbilicus in new-born children; further, erysipelatous inflammation, or a modification of it, may attack parturient women. Idiopathic erysipelas occurs most frequently on the face. That erysipelas is highly contagious among surgical patients, and that its presence in a lying-in hospital induces a rapidly fatal form of puerperal fever among the mothers, and erysipelas of the new-born infants, are facts entirely beyond dispute. It is obvious that in these cases the disease is propagated by the transmission from the sick to the healthy of some poisonous matter capable of reproducing it; and from the circumstance that the inflammation always begins at the very spot where a wound or rawness exists, it is reasonable to assume that the poison has been inoculated at that spot. It is by no means clear that erysipelas spreads in the same way to those whose skin and mucous involutions are sound. No doubt many, and apparently very striking, examples of such spread are recorded, but, on the other hand, good authorities deny its occurrence, and certainly it is far from common.

In close relation with the subject just considered is the question, whether erysipelas is to be regarded as a specific fever or a mere local inflammation. The former view is generally entertained, at all events in this country; and the chief grounds on which it rests are: first, the manifest contagiousness of the disease under certain conditions; second, the existence, which is obvious in idiopathic cases, of a distinct, though short, stage of incubation; third, the affirmed enlargement and tenderness of lymphatic glands prior to the appearance of the skin affection, indicating that the erysipelatous inflammation is secondary to constitutional disturbance; fourth, the discovery of bacteria in great abundance in the inflamed tissues and in the lymphatic spaces and vessels connected with them, and the fact that these bacteria may be propagated, with the inflammation which they accompany, by inoculation upon the lower animals; and lastly, the close resemblance which exists between the general morbid anatomy and symptoms of this disease and those of the specific fevers. The arguments in favour of its being a non-specific and local disease are chiefly the following:—first, the fact that the disease appears in many cases to arise from exposure to cold and various other non-specific causes; second,

that a previous attack, so far from precluding subsequent attacks, as is generally the case with the infectious fevers, encourages them, as is the common rule with non-specific inflammations; third, that contagiousness is not an attribute of the specific fevers only, for many varieties of simple inflammation (catarrh, ophthalmia, and the like) are apt to spread by contagion; and lastly, that the symptoms and morbid processes which attend erysipelas can be fully accounted for as being the consequences of the local inflammation.

On the whole, if all the different forms of inflammation commonly called erysipelas are really manifestations of the same disease, erysipelas, even when it occurs in the sporadic form, must be a specific and contagious fever. At the same time there can be no doubt that among predisposing causes must be included, not only breaches of surface, and local irritations of various kinds, but also exposure to cold and to atmospheric changes, and constitutional conditions, such as may result from poor living and long-continued indulgence in drink.

*Morbid anatomy.*—The earliest local changes consist in a circumscribed blush of more or less vivid redness, which fades on pressure, and the accumulation of inflammatory products (lymph and corpuscles) in the substance of the cutis and subcutaneous connective tissue. The inflamed patch consequently becomes thickened, hard, and brawny. Its margin is well defined, and obvious to eye and touch. The character of its surface varies according to the part affected. If the skin be originally smooth and delicate, it becomes yet smoother, and shining; if it be coarse, all its markings are apt to get magnified, and its coarseness therefore exaggerated. The inflammation gradually spreads by continuity to the surrounding healthy parts, and thus extending may ultimately involve a very large area—the entire surface of a limb, for example, or that of the head and face, and occasionally (it is said) that of the whole body. As it spreads, however, the parts first affected undergo changes, their tension diminishes, their redness becomes less vivid and assumes a yellowish or brownish tint, and resolution, preceded by desquamation, presently takes place. Thus all stages of the disease may be present at the same time. Occasionally erysipelas (then termed *erratic*) disappears from one part and breaks out elsewhere, and may thus be prolonged by successive outbreaks.

The intensity and results of the inflammatory process vary considerably in different cases. In some the degree of inflammation present is no greater than that attending the affections which we shall shortly describe under the name of erythema. In some the effusion is so abundant that it infiltrates the subcutaneous connective tissue, and well-marked œdema is developed. This is common wherever the cutis is thin and the subcutaneous connective tissue lax, as they are in the eyelids and scrotum. In some cases the inflammation goes on to the formation of pus, which, like the œdema, occupies mainly the subcutaneous tissue. The suppuration is frequently diffused; but sometimes, and especially in the eyelids, and elsewhere about the face and head, forms circumscribed abscesses.

In some cases again, and mainly in connection with suppuration, the connective tissue sloughs, or the skin itself becomes gangrenous. When œdema, suppuration, or sloughing is in progress, the inflamed surface becomes paler and duller, perhaps livid, and acquires a soft 'boggy' feel, or pits on pressure. Vesicles and bullæ not unfrequently form on erysipelatous surfaces, and may become converted into pustules. Subsequently excoriations and scales or crusts necessarily make their appearance. Bullæ also, containing sanious fluid, attend the progress of superficial gangrene and subcutaneous sloughing.

Although erysipelas is commonly limited in depth by the fasciæ, it is not invariably thus limited; and hence subjacent organs are apt to get involved. Thus erysipelas of the trunk may produce inflammation of the peritoneum, pleuræ, or pericardium; erysipelas of the neck œdema of the larynx; and erysipelas of the head meningeal inflammation. Again, it not unfrequently creeps from the skin into the mucous orifices: into the auditory meatus, causing inflammation of the ear; or into the nose or mouth, and thence to the fauces and larynx. On the other hand, cutaneous erysipelas may result from extension of faucial, aural, and other such inflammation.

There is a marked tendency in erysipelas for the veins, and especially for the absorbents, to suffer. As regards the absorbents, indeed, it is not only common to trace red lines from the seat of inflammation to the nearest glands, which get enlarged and tender; but some authors go so far as to maintain that a patch of erysipelatous inflammation is always preceded by inflammatory enlargement of the neighbouring lymphatic glands. Phlebitis, again, with suppuration in or around the veins, and pyæmia, occasionally take place.

Repeated attacks of erysipelas lead to permanent thickening and induration, and sometimes to very considerable overgrowth, of the skin, and subjacent connective tissue. Indeed, according to Virchow, it is to such attacks frequently repeated that the hypertrophy of these parts in elephantiasis is mainly due.

There is no special affection of internal organs in erysipelas. In the early stages of the disease the blood contains an excess of fibrine and white corpuscles; but subsequently it tends to assume the characters commonly observed in the later stages of febrile disorders. Post mortem it is generally found dark, and fluid or pitchy, with little tendency to coagulate, and still less to the separation of fibrine. It stains the inner surface of the heart and vessels. The organs are generally soft, and the lungs, liver, kidneys, and especially the spleen, congested. Pneumonia is not uncommon. Decomposition is rapid.

*Symptoms and progress.*—The symptoms of erysipelas are mainly those of the local process and of inflammatory fever; but they are often complicated with those of intercurrent lesions; and they vary in their severity, both actually and relatively, according to the intensity of the inflammation, its extent, and its situation. In idiopathic erysipelas the local signs are generally preceded by an interval, varying from a few hours

to two or three days, in which the patient experiences slight febrile symptoms, sometimes rigors; and in which, according to certain authors, some swelling and tenderness of lymphatic glands may be detected. At the end of this time an inflammatory blush appears, generally on some part of the face, attended with heat and tingling, and tenderness on pressure. With the appearance and extension of this, the febrile symptoms increase; there are headache and pains in the limbs, rise of temperature with dryness of skin, rigors, increased rapidity of pulse, furring of the tongue, with thirst, loss of appetite and nausea or sickness, generally some constipation, occasionally, however, diarrhœa, and scanty high-coloured urine. There may be some degree of drowsiness, but sleep is restless and disturbed by dreams. If the case be mild, the symptoms may subside and the patient become convalescent in the course of two or three days. But if the inflammation continue to spread, or in any way to increase in severity, the pulse gets rapid and feeble, the respirations hurried, the tongue more thickly coated and dry; and delirium, at first only when the patient is dropping to sleep or waking, but subsequently constant, comes on. Sometimes at this period diarrhœa occurs; and the patient's evacuations may be passed into the bed. At this point also (that is, at the end of six or seven days) the patient may begin to amend. When, however, from the inherent severity of the attack or other circumstances, the case takes an unfavourable course, the symptoms assume a more distinctly typhoid character; marked mainly by great failure of muscular power, tremulousness of limbs, dry black tongue, want of control over the evacuations, and delirium, which is generally low and muttering, sometimes busy like that of delirium tremens, and occasionally violent and maniacal. As the fatal end approaches the temperature often rises, the skin becomes bathed in sweat, the pulse rapid, perhaps irregular, and almost imperceptible, the respirations quick and noisy, and the delirium passes into coma.

The temperature in erysipelas is always above the normal, but rarely exceeds  $106^{\circ}$ ; and, although it is liable to considerable variation, there is a general tendency to an evening rise and a morning fall. The urine is always scanty, presents an excess of urea and diminution of chlorides, and often contains small quantities of albumen between the fourth and seventh or eighth day of the disease. The motions are generally dark-coloured, watery, and fetid. The course and event of the disease are often modified by the association with it of some one of the various complications which have been previously enumerated. Thus, œdema of the larynx and congestion of the lungs will each add symptoms and dangers of its own. And similarly inflammation of the membranes of the brain, phlebitis and pyæmia will each bring its characteristic indications. Further, the health and circumstances of the patient at the time of seizure for the most part largely modify the character and severity of his attack.

Erysipelas which seems to affect only the cutis is termed *simple erysipelas*; when the subcutaneous connective tissue is largely involved as well, the affection is called *phlegmonous erysipelas*; when œdema, suppu-

ration, or sloughing supervenes, the erysipelas is often termed *edematous*, *suppurative*, or *gangrenous*, as the case may be. But these distinctions are essentially artificial, for the various forms of erysipelas run into one another, and several, or all of them, may be present at the same time in the same case.

*Treatment.*—Having regard to the tendency which erysipelas has to become contagious, it is always important that erysipelatous patients should be removed from the neighbourhood of those who are especially liable to take it; and that, in fact, all such precautionary measures should be adopted as have been already recommended in relation to the infectious fevers. The local treatment in mild cases is of little importance; and, even in severe cases, has perhaps little influence. Collodion, nitrate of silver in saturated solution, solution of sulphate of iron, tincture of iodine, and mercurial ointment, have each been strongly advocated. Flour, dusted thickly over the surface, is also recommended. There is an obvious disadvantage in employing anything which conceals or masks the diseased surface; for which reason several of the above applications are objectionable, even if useful on other grounds. Mild astringent lotions and ointments, such as those of lead, zinc, and iron, are probably as useful and convenient as any. Cold-water dressing, which has commonly been discountenanced in this country, is strongly recommended by Hebra, and is undoubtedly useful. Warm applications and poultices are not generally desirable. It is rarely needful to abstract blood locally, or to make incisions, except for the purpose of letting out matter, or relieving tension. In reference to the internal treatment of the disease, we must recollect that mild cases get well spontaneously, and that more serious cases very soon present symptoms indicative of great debility and blood-poisoning. For these reasons it seems obvious that depletion can never be necessary, but that, as a rule, the strength of the patient should be sustained, and the free action of his excretory organs encouraged. To support strength, such nourishment as he can take should be administered frequently and in small quantities. Milk, eggs, beef-tea, arrowroot, sago, and the like, are most suitable for the purpose; to which, if the pulse be failing and the tongue dry, brandy, wine, or ale (if the patient prefer it) should be added. To promote the action of the emunctories, purgatives should, if necessary, be from time to time administered, and the patient may be put on a course of mild diuretics or diaphoretics. Ammonia, camphor, iron, quinine, have all been employed in the treatment of erysipelas. It is questionable, however, whether any one of them is of material use in the early stages of the disease. But stimulant medicines are clearly indicated when typhoid symptoms are present; and tonics are, of course, highly valuable during convalescence. Hyoseyamus and opium are not generally indicated, and must always be given with caution. But in cases where there is great irritability, or persistent want of sleep, they, chloral hydrate, or other sedatives are valuable.

III. CARBUNCLE (*Anthrax*). BOIL (*Furunculus*)

*Definition.*—A boil or carbuncle is an intense inflammation occupying, within a well-defined area, the entire thickness of the skin (inclusive of the subcutaneous connective tissue), and attended almost always with circumscribed suppuration and the formation of a slough.

*Causation.*—Boils and carbuncles are usually considered to be constitutional disorders ; and undoubtedly they are common in persons of broken-down constitutions, and in those who are recovering from diseases of various kinds. Diabetic patients are said to be specially liable to them. But, on the other hand, they are common in those who appear to be otherwise in perfect general health ; often occurring in connection with acne and other forms of skin disease, or induced by local irritation, such as arises from friction, poulticing, the contact of unhealthy discharges, and (as pathologists know to their cost) the soakage of dead bodies. It cannot be denied that there is, in many cases, a predisposition to boils and carbuncles, and that this predisposition may be induced. We are disposed, however, to regard the disease as essentially local, and due to the operation of local causes ; and to believe that, like acne, it is mainly an affection of the sebaceous glands and their surroundings.

*Morbid anatomy.*—The morbid process commences with circumscribed thickening and induration of the deeper tissues of the skin, attended from the beginning, or soon followed, by a little elevation and redness of surface. The resulting nodule increases in area and thickness, and consequently in prominence, until, at the end of a few days, it has attained its full development. It then presents a more or less circular base, varying in diameter from half an inch to three or four inches or more ; is intensely congested, and surrounded with an areola of congestion and often much œdema ; and forms a considerable elevation which is conical or flat, according as the area involved is small or large, and presents on its summit a vesicle or group of vesicles, containing serous or sanious fluid or pus. Each vesicle soon bursts, discharges its contents, and exposes in its floor a small round orifice, from which, even at this time, an ash-coloured slough protrudes. When there are more vesicles than one, they generally soon run together ; and then by sloughing of the intervening papillary layer of the cutis the subjacent orifices coalesce, so as to form a more or less extensive irregular excavation, the floor of which is formed as are the floors of the primary orifices by underlying sloughy tissue. The slough thus exposed has been gradually forming during the progress of the disease, and involves the deeper structures of the skin and sometimes subjacent parts : mainly, however, it consists of connective tissue saturated with pus, and presenting a yellowish or greyish colour, and a resemblance to washleather. It now gradually becomes detached from its bed, and is at length discharged through the orifice which has formed over it. After its separation the excavation which it leaves granulates, the inflammatory thickening of the surrounding tissues subsides, and the parts gradually return to their normal condition, except that a permanent

scar remains. The distinction between a boil and a carbuncle is arbitrary; a boil is comparatively small, generally conical in shape, and opens by a single orifice; a carbuncle is characterised by its larger size and flatness, and particularly by the formation of more orifices than one, and the presence of superficial gangrene. Carbuncles very often arise in the median line of the trunk behind, and especially in the nape of the neck. They sometimes attack the lips (more particularly the upper lip), and are then characterised by great malignancy. The lymphatics and veins are very apt to get inflamed in these affections; and, of carbuncle especially, pyæmia is a common sequel.

*Symptoms.*—The local symptoms are heat, tingling, and aching, with throbbing and great tenderness, which are often followed by pain and redness of the lymphatic vessels and glands in relation with them. There is generally, even with a boil, some amount of febrile disturbance; and with a carbuncle the febrile symptoms may be very severe. Indeed, in the latter case, the general symptoms are almost exactly like those which attend the progress of erysipelas, and may at least be as serious as those of the worst forms of that disease, and the consequences may be fully as grave and fatal.

*Treatment.*—The general treatment of carbuncle is identical with that of erysipelas. For local treatment free incisions are generally recommended, which, if the carbuncle be large, should be crucial. Pain and tension are greatly relieved by them; but it is doubtful if they check the progress of the disease or materially modify its course. Caustic applications, and especially the free use of caustic potash, are recommended by some. Poultices and warm water dressings are generally of service. Hebra strongly advocates the employment of cold in the form of compresses saturated with ice-cold water, to be applied so long as they are not disagreeable to the patient.

In the treatment of boils, which often show a tendency to recur, many internal medicines (among others yeast, quinine, and mineral acids) have been recommended, with the object of preventing that recurrence. But it is more than doubtful whether any of them has a specific influence. It is, of course, always desirable to treat any associated malady which may tend to keep up a condition of system favourable to the development of boils. Boils may be dealt with locally on the same principle as carbuncles; and some authorities believe they may be made to abort by the early application to them of strong ammonia, caustic potash, acid nitrate of mercury, or some other such agent.

---

## IV. ERYTHEMA. ROSEOLA. URTICARIA. PITYRIASIS

*Causation and description.*—The above affections embrace a considerable number of morbid states of the skin which resemble one another in the facts: that they are for the most part slight, superficial, and essentially short-lived inflammations; that they have little or no tendency to suppuration, ulceration, or gangrene, but end usually in furfuraceous desquamation; that they are often variously figured and distributed; and that they are never contagious.

There is great confusion amongst dermatologists as to the distinctions between erythema and roseola. Willan describes the former as a nearly continuous redness of some portion of the skin, and the latter as a rose-coloured efflorescence variously figured. But even he includes under the head of 'erythema' affections which, according to his definition, should be varieties of roseola; while, on the other hand, several conditions are now universally termed roseola which, according to the same definition, ought to be regarded as erythema—we refer to so-called 'roseola cholERICA' and 'roseola vaccina.' The formation of wheals is the special characteristic of urticaria; but wheals arise under so many different conditions, and so closely resemble some of the eruptions which are termed erythema, that it is impossible to draw any sharp line between them. For these reasons we propose to discuss erythema, roseola, and urticaria together; and, although we shall preserve the names, we shall regard them as indicating trivial, and in some cases imaginary, distinctions between things which are essentially the same. Pityriasis we look upon as simply the desquamating stage of the different forms of erythema.

Some of these affections are of local origin, due to the action of direct irritants; but many of them, as is shown by attendant circumstances and by their simultaneous development in different parts, are distinctly traceable to causes acting from within. The former, if extensive, may be attended with febrile disturbance. The latter are generally so attended; and, indeed, not unfrequently appear in the course of some rheumatic, gouty, or other inflammatory or febrile attack. The local symptoms are, for the most part, more or less intense itching, burning, stinging, and occasionally aching.

A. *Erythema simplex* is a pretty uniformly diffused redness, occupying an area of irregular size and form. The redness is generally bright, disappearing on pressure; is attended with slight thickening and elevation of the skin; and presents a fairly well-defined margin. It often spreads from its primary seat over the neighbouring skin, and is not unfrequently erratic. There is a very close resemblance between certain varieties of erythema and the simplest form of erysipelas; between which, indeed, it is impossible in many cases to distinguish. One variety of erythema is produced by the direct operation of local irritants, as by the application of a mustard plaster, or by the constant flow of catarrhal secretions

from the nostrils or of saliva from the mouth, and in children, when from want of cleanliness the urine is allowed to fret the thighs, groins, and other neighbouring parts. Intimately related to this is the condition known as *e. intertrigo*, in which inflammation is induced, either by attrition of opposed surfaces of the skin, or by the effect on such surfaces of the decomposing and fetid sweat which accumulates between them. This is common in children and fat adults in the groins and between the upper parts of the thighs and external genital organs; and in fat women between the pendulous mamma and the surface with which it lies in contact. The persistence of the cause in *e. intertrigo* tends to keep up and intensify the irritation; and consequently excoriation and ulceration are apt to supervene. Another variety of erythema is termed *e. lœve*. This is the superficial inflammatory blush which often appears in limbs, and especially in legs, which are the seat of anasarca. The redness is generally somewhat uniformly distributed, and is attended with tenderness and itching, tingling and aching. Vesicles, which rupture and allow of the escape of the dropsical fluid, are apt to form on the surface; and not unfrequently the inflammation passes into distinct erysipelas, or superficial gangrene ensues. A further variety of erythema is known by the name of *pityriasis simplex*. This occurs on various regions of the body, but is especially common in the form of circular or oval patches on the lips, chin, and other parts of the face, in children and persons of delicate skin. The patches present a slight degree of redness, and are early covered with thin branny scales, or scurf, whence the name 'pityriasis' has been given to them. This affection is also of common occurrence in the hairy scalp, when it is usually called *p. capitis* or *dandriff*. In this case the branny scales, which form pretty abundantly, and, owing to the presence of hair, tend to accumulate, contain, as might be expected from their soil, a large admixture of sebaceous matter.

B. *Erythema multiforme*.—Under this term, which we owe to Hebra, are included *e. papulatum* (in the sense in which Hebra employs that term), *e. circinatum*, *e. iris*, *e. marginatum*, and *e. gyratum*. The earliest stage of the affection is characterised by the appearance of small, flat, circular, congested elevations of the cutis, attended with itching, and differing little if at all from wheals (*e. papulatum*). Their development may cease at this point. But in most cases they pass on to a second stage: the wheal gradually increases in area until perhaps it measures half an inch or an inch in diameter; and, while thus increasing, its central portion probably subsides, its periphery forming a congested tumid ring (*e. circinatum*); or the enlargement of the inflamed patch is effected by the development of successive concentric rings of inflammation, separated by zones of fairly healthy skin, and the affection known as *e. iris* results. Further, the spots of *e. papulatum*, and the patches of the circinate form of the affection, which may attain much larger dimensions than have been above assigned to them, tend in the course of their development to coalesce with one another, and thus to cover with more

or less uniformity round, oval, or sinuously margined areas of several square inches, which, like the spots from which they sprung, are still for the most part characterised by a tendency to central subsidence, and marginal extension by a broad band of congestion. In their progress these 'fairy rings' not unfrequently break up into segments, and hence after a while curved or sinuous erythematous bands alone remain. These latter forms of the affection constitute *e. marginatum* and *e. gyratum* respectively. The several varieties of erythema above described occur on different parts of the body and are sometimes very extensively distributed; they are most common, however, on the backs of the hands and wrists and corresponding parts of the lower extremities. They are generally attended with febrile symptoms, which, if the eruption be extensive, may run high—the temperature rising temporarily to 104° or more; and they are apt to be associated with rheumatism or gout. Individually the inflamed patches seldom last more than a week or ten days, sometimes not longer than two or three days, and terminate in desquamation. But the eruption may be continued by successive crops for several weeks. Occasionally it assumes a chronic form, and the patient remains for years liable to more or less frequent outbreaks. It sometimes happens: that the wheals or rings become the seat of intra-cutaneous hemorrhage (*purpura urticans*?), which generally occurs in the form of minute coalescing points, and is for the most part limited to their central areas; and that this leads to the death of the involved cutis and separation of the eschars, or to the development of sanguinolent blebs, and unhealthy ulcers. Further, vesicles or bullæ, containing limpid fluid, not unfrequently arise in more or less abundance upon the surface of the erythematous patches, constituting varieties of *herpes* and *pemphigus*.

C. *Erythema nodosum* is characterised by the appearance of round or oval red patches, varying, roughly speaking, from  $\frac{1}{2}$  inch to  $1\frac{1}{2}$  inch in diameter. They rise in a lenticular form above the surface in relation with which they are developed, and are consequently most elevated at the centre, where also their redness is most intense; and in both of these respects they fade away gradually at the margins. They are hot, hard, and tense to the touch, and to the patient tender and attended with aching. They occur chiefly scattered over the anterior aspect of the leg, between the ankle and knee, but sometimes on the lower part of the thigh. They occasionally appear also on the corresponding parts of the arms, and in rare cases stud the whole of the surface of the body, including fingers, toes, and face. The patches generally increase in number for a few days—each one lasting perhaps a week. They get dusky in colour after a day or two, and generally acquire a bluish aspect when exposed to cool air; they present successively the greenish and yellowish tints of fading bruises, and end with desquamation. *E. nodosum* is for the most part preceded by and attended with febrile symptoms, and not unfrequently associated either with rheumatic pains or with distinct rheumatism. It is most common in young persons, especially females, above the age of puberty. The affection

described by Willan under the name of *c. tuberculatum* is merely a modification of *c. nodosum*. We believe, too, that the *roscola autumnalis* of the same author is essentially the same disease; and may add that there is little, if any, difference between a *chilblain* (*pernio*) and a patch of *c. nodosum*.

D. *Erythema fugax* is the name given to the evanescent patches of redness which appear on the face, neck, chest, and other parts, in hysterical and dyspeptic patients. This is closely related to the patches of redness, termed *roscola*, which are sometimes observed in cholera, small-pox, and other fevers, and may be held to include those which are so commonly associated with the vesicular and other inflammatory skin diseases of young children.

E. *Roscola*, as has already been explained, is a name of common and somewhat indefinite application. This, or still better perhaps the name *r. rubecoloides*, may properly be applied to an affection of the skin, of which Willan seems unnecessarily to make two varieties, namely *r. aestiva* and *r. infantilis*. This rash seems generally to be preceded for a day or two by slight febrile disturbance, and, like so many other rashes, to make its appearance first on the face and neck, whence it quickly spreads over the general surface of the skin. It consists of rose-coloured flatly elevated circles, fading at the periphery into the surrounding healthy skin, and disappearing on pressure, varying perhaps from  $\frac{1}{8}$  to  $\frac{1}{2}$  inch in diameter, and often running together over extensive tracts so as to form an imperfect network with scalloped interstices. There is often some general but slight tumefaction of the surface, and a passing chill is apt to render the rash temporarily of a peculiar violet tint. Itching is frequently complained of, and the fauces are sometimes implicated. The affection disappears within four or five days after the first appearance of rash. It is unattended with danger, and is of little importance, but for its resemblance to measles and r  theln or epidemic roseola on the one hand, and to urticaria on the other.

F. *Urticaria* or *nettle-rash* has been subdivided by dermatologists into numerous varieties. It seems unnecessary, however, to make more than two, namely, *u. acuta* or *febrilis*, and *u. chronica* or *evanida*.

The more common form of the disease is *u. febrilis*. In it the appearance of the eruption is often, if not always, preceded by febrile disturbance, with probably some degree of gastro-intestinal derangement; and these symptoms continue during the prevalence of the eruption, which rarely exceeds a few days or a week. The rash, which is attended with much local heat and itching, generally comes out in the evening or night, and disappears in the morning, and is continued for a few days by successive nocturnal outbreaks. In many cases, however, it appears at irregular intervals both night and day. The wheals arise quickly, seldom remain out longer than a few hours, and on subsiding sometimes leave behind them a slight yellowness of skin and a tendency to desquamate. They may appear simultaneously or in successive crops on any or all parts of the body; but are most common on the face, back, front of the chest

and flexures of the joints. The lips, tongue, and interior of the mouth are occasionally affected. The wheals are sometimes scattered, but are more generally clustered and running together, and may then cover large tracts. Their presence is often attended with subcutaneous cedema, and stiffness of parts. Scratching and other forms of local irritation tend to increase their size, number, and duration. Occasionally febrile urticaria is due to the use of certain alimentary substances, such as shell-fish and pork, which, either from some acquired poisonous quality, or from some idiosyncrasy in the subject, act in a special way on the system. In severe cases the symptoms come on rapidly, are very grave, and indeed may prove fatal. They are mainly rigors, failure of circulation, fainting, precordial oppression, vomiting, and difficulty of breathing. They generally subside, however, in the course of a few hours.

*Chronic urticaria*, which supervenes in some cases on the acute form, is generally unattended with marked fever. It shows itself for the most part, like that, in successive crops of eruption, which come out daily or at irregular intervals, for weeks or months, sometimes for many years. A curious sub-variety of chronic urticaria is that which Sir W. Gull has termed *factitious urticaria*. Here the eruption, although it may come out as in other cases in successive crops, is also readily produced by pressure or irritation. And thus the application of a ligature, or the passage of the finger-nail, is followed in a few seconds by the appearance of a line of confluent wheals, with an areola of congestion, which remains out for a minute or so and then disappears.

Wheals, resembling those of urticaria are often due to the operation of local irritants. They are common in prurigo, scabies, and phthiriasis. They result from the prick of the ordinary stinging-nettle, and from the action of some species of jelly-fish. And they follow the bites of many insects, such as gnats, fleas, and bugs. In this last case, however, the wheals are persistent, and often last for a week or ten days. They probably constitute Willan's *urticaria perstans*.

The causes of urticaria are not well understood. Some of its severer forms are caused by poisonous matters received into the stomach, and acting through the medium of the circulatory system. It is natural, therefore, to assume that other forms of urticaria must be due to gastrointestinal disturbance. That in many cases it really is so is probably beyond doubt. But it is equally certain that, in a large number of instances, especially of the chronic variety of the disease, there is no indication whatever that the digestive functions are at fault. Mental emotion, hysteria, and uterine affections are sometimes assigned as causes of urticaria.

*Treatment*.—Most of the erythematous inflammations just described need little or no special treatment, either local or general. Many of them must be regarded as parts, and indeed trivial parts, of more serious diseases, such as rheumatism; and their treatment must merge in that of the more general malady with which they are associated. For most of them cooling or astringent lotions, such as cold water or lead-wash, are service-

able and agreeable; but for some of them, more especially *e. intertrigo* and pityriasis, careful local treatment is generally essential. In *e. intertrigo* the affected parts should be kept perfectly clean and free from acrid moisture, and opposed surfaces separated, if necessary, by a piece of lint anointed with some appropriate ointment. Dusting the surface with starch, oxide of zinc, fuller's earth, lycopodium, or violet powder, and applying astringent lotions or ointment, are often valuable measures. In pityriasis cleanliness is equally essential, and the cure is often aided by the use of mild mercurial ointments. When the lower extremities are affected with *e. nodosum* or *e. leve*, the patient should keep the recumbent position, with the legs elevated. The general treatment of these various affections when acute should be mildly antiphlogistic, and comprise cooling drinks and gentle laxatives. In *e. nodosum*, however, it is frequently necessary to have recourse to tonics. In *e. multiforme*, when it has assumed a chronic form, tonics are also indicated. And in urticaria, if it be either severe or persistent, special measures must be adopted. If, for example, there be reason to suspect its dependence on poisonous substances taken into the stomach, an emetic or a purgative may be necessary; if there be much abdominal pain, opiates; if collapse, ammonia, brandy, or other stimulants. In the chronic form of the disease few remedies have been found generally useful; but arsenic, mineral acids, alkalies, tonics, and change of air have often been recommended.

## V. PSORIASIS (*Lepra*). PITYRIASIS RUBRA

*Causation and description.*—We have shown that one of the events of the different forms of erythema is the formation of scurf; we pass, therefore, naturally from their consideration to that of psoriasis, which is essentially also a superficial inflammation of the skin, attended with the development of scales. It is thus closely related to pityriasis, and cannot always be separated from it. Willan and his followers have distinguished psoriasis from lepra, but their distinctions are artificial; and we shall therefore, with Hebra and others, combine them in a common description.

A. *Psoriasis* is characterised by the presence of defined, mostly circular tracts, in which the cutis is somewhat congested and raised; while the epidermis over it is thickened and opaque, and tends to come away in large flakes. These, on their separation, leave behind a congested, irritable, and sometimes slightly excoriated surface, on which squamæ are speedily reproduced.

Psoriasis commences with spots or discs of slight congestion, over which, almost from the earliest moment, the cuticle assumes a scaly character; but at first, and while they are in process of enlargement, the area of congestion usually extends beyond that of desquamation.

The patches vary in size and shape. In some cases they are mere papules, a line or less in diameter; in some they have a discoid form,

measuring between  $\frac{1}{4}$  and  $\frac{1}{2}$  inch across ; in some they form rings between (say) the size of a shilling and that of a crown-piece, enclosing a central area of comparatively healthy skin, which (especially if they become large) tend to break up into segments ; in some cases, again, partly by coalescence of adjoining patches, partly by innate irregularity of growth, they form tracts of large size and irregular outline, covering, it may be, an entire limb or even the whole surface of the body.

The squamæ also vary in colour, consistence, thickness, and form. These peculiarities are mainly due to the different degrees of rapidity with which they are developed, and to the fact that they result from an excessive formation and exfoliation of epidermis, among the cells of which inflammatory exudation and even the contents of the involved cutaneous glands are diffused in various proportions. The scales are sometimes white and glistening, like mother-of-pearl ; sometimes yellow, and more or less waxy in appearance ; sometimes brown or black ; sometimes close and dense in texture ; sometimes friable and flaky, or even powdery. In some cases they form an extremely thin layer, in others they are a quarter of an inch or more in thickness ; and occasionally, when a virgin patch has been slowly enlarging, the accumulated scales on its surface assume the form of a limpet-shell. The general outline of the crust will necessarily be determined by that of the patch on which it is produced.

The subjacent skin is always more or less distinctly congested and thickened ; and generally, when the disease is in an aggravated form and has existed for some time, tends to get excoriated and fissured, and then to exude serum and blood, which, mingling with squamæ, form distinct scabs.

The eruption of psoriasis is peculiarly liable to attack the extensor surfaces of the knees and elbows. But it may occur on any part of the person, though it is comparatively rare on the face, and still rarer on the palms and soles. The hairy scalp is a common seat of the disease. The nails also are not unfrequently involved, becoming thick, rough, and coarse in texture. It is very apt to be symmetrical.

Psoriasis presents, as may be supposed from the above account, many varieties of character, some of which it may be useful to remember, if only for descriptive purposes. Thus, when it consists of an eruption of numerous small spots, it is called *p. guttata* ; when of small discs covered thickly with white scales, *lepra alphoides* or *alphos* ; when of rings, *l. vulgaris* ; when of segments of circles which have coalesced with similar segments of adjoining circles, *l. gyrata* ; and when of irregular patches occupying a large area, *p. diffusa*.

The progress of psoriasis is occasionally remarkably acute ; thus, it will sometimes come out and become general in the course of a week, and disappear with almost equal suddenness at the end of two or three weeks. At other times, and much more commonly, it is a chronic malady ; sometimes remaining for years in two or three situations, as, for example, on the knee or point of the elbow, and presenting periodical exacerbations in

the spring or autumn; sometimes occupying large tracts of surface persistently (*p. inveterata*) for many years, or for life.

The general health of patients suffering from psoriasis is rarely materially or even obviously impaired. Occasionally, however, febrile symptoms attend its acuter manifestations, and sometimes debility and emaciation supervene in the course of long-continued severe attacks. Yet the remarkable tendency of the eruption to break out simultaneously in corresponding situations on both sides of the body, and its undoubtedly hereditary character, together with the fact that an almost identical eruption attends the constitutional operation of the syphilitic virus, point very strongly to the dependence of psoriasis on constitutional causes. Its development and disappearance are indeed often manifestly influenced by constitutional modifications. Thus it occasionally shows itself only during pregnancy, disappearing with the birth of the child; and, on the other hand, those who are subject to it may lose it entirely during the period of child-bearing. It is remarkable how little local discomfort, comparatively, psoriasis produces: a little stiffness and a little itching are often the only inconveniences complained of.

B. *Pityriasis rubra*.—This term was applied by Willan to a variety of that form of pityriasis already briefly considered under the head of erythema. Hebra, and in this respect we follow him, employs it to designate a specific form of skin disease, of rare occurrence, and having a close affinity with psoriasis. So far as is known, it appears to commence with universal congestion of the skin, soon followed by general tendency in the epidermic layer to separate in scales. The redness of the cutis, when once established, persists, but is attended with little thickening or discomfort; and the epidermis continues to desquamate, the scales, however, sometimes accumulating in considerable quantity. When fully developed, there is nothing except the history and progress of the malady to distinguish it from universally diffused psoriasis. *Pityriasis rubra* is always a chronic disease, and one which only rarely ends in recovery. As a general rule, patients who suffer from it remain in other respects fairly healthy; but elderly persons are apt to emaciate, to become cachectic, and to sink from exhaustion.

*Treatment*.—The local treatment of psoriasis consists, first of all, in the removal of the scales, which may be effected by warm baths or poultices, or by thorough inunction of oil or ointments of various kinds; and then in the application of special remedies, among which may be included iodine paint, nitrate of silver, strong solution or ointment of subacetate of lead, and especially tar ointment, or other equivalent empyreumatic preparations. The persistent use of warm baths for several hours daily is often of great value. The constitutional treatment most generally resorted to is the exhibition of arsenic in small repeated doses. Tar is often administered internally with the same object; as also are tincture of cantharides, copaiba, iodide of potassium, and phosphorus. Tonics and cod-liver oil are occasionally useful. The disease, however, is very apt to resist all treatment; and even when a cure seems to be effected it

is very often only apparent, and the result of the normal periodic retrogression of the malady. The treatment of pityriasis rubra may be conducted on the same principles as that of psoriasis.

---

## VI. ICHTHYOSIS (*the fish-skin disease*)

*Description.*—Under this term are included certain affections of the skin, characterised by dryness of the epidermis, with tendency to crack and scale, deficiency or absence of the sebaceous secretion, and more or less horny conversion of the epithelium of the sebaceous follicles.

A. *Ichthyosis simplex*, or *xerodermia*, is the commonest variety of the affection. It is for the most part congenital, and its presence is generally first recognised by the parents during the first year or two of life, in consequence of the harshness and dryness of the general surface of the skin, and the difficulty they experience in keeping certain parts of it, such as those covering the elbows and knees, in a cleanly condition. In quite young children, indeed, it only manifests itself by the characters just enumerated, and by the tendency of the epidermis to come away in flakes. As life advances the condition of the skin becomes more characteristic. The affection is then seen to be general, but differing in severity in different parts. It is usually least marked on the palms and soles, and on the inner aspects of the wrists, arms, and thighs. Here the skin may be a little dry only, and scarcely differing in appearance from healthy skin. The face is generally rough and dry, and slightly furfuraceous; and the lobes of the ears and the palpebral orifices are occasionally deformed. But the greater part of the rest of the surface of the limbs and trunk is mapped out into irregular polygonal *aræ*, the limits of which are, for the most part, determined by the normal creases and folds; and the epidermis of these *aræ*, dry, hard, brittle, and somewhat nacreous, becoming partially separated at the edges, and sometimes undergoing complete separation, gives that scaly character to the surface which allies this disease anatomically to psoriasis. Occasionally the creasings on the trunk are so coarse and deep, and the *aræ* of epidermis between them so large, symmetrical, and thick, that the patient's body presents a striking resemblance to that of an alligator. But the places in which ichthyosis involves the most striking results are generally the knees, elbows, and those other parts of the surface which are naturally apt to get thickened under the influence of pressure or friction. Here the epidermis becomes extremely thick and hard, generally brown or black from impregnation with dirt, and divided even more manifestly than elsewhere into polygonal *aræ*. Wilson states that in this affection many of the sebaceous glands are filled with a dry hard substance, which often projects from their orifices.

A condition of skin closely resembling ichthyosis is often met with in the course of chronic wasting diseases, such as phthisis, and is sometimes developed with advancing years.

Persons who suffer from ichthyosis are said to be, for the most part, feeble and emaciated. But that is certainly not a universal rule. They are often liable to eczema and impetigo.

B. *Ichthyosis cornea* is a much rarer affection than the last, and often arises at a later period of life. It is seldom general, but usually appears in scattered patches which have a tendency to spread. It is characterised by the development of prominent, hard, dry, horny processes of epidermis, which often have an exact resemblance to those occupying the surface of the knee in the simple variety of the disease. These are usually grouped together, and hence individually often assume an irregular prismatic form; and they project sometimes half an inch or more above the general surface. They are partly due to a mere growth of epidermis in patches, corresponding to the normal polygonal area of the skin, but are largely connected with the horny conversion of the epidermic lining of the sebaceous follicles. In the latter case the horny outgrowth first appears as a comedo-like body, which distends the orifice of the follicle, and then rises above it in form not unlike a caraway seed. Presently this gets detached or broken, but the horny matter, still growing upwards and in breadth, distends the sebaceous follicle and its orifice more and more, until they form a mere shallow pit, surrounded by a tumid ring. With the progress of the disease the pit is effaced; what was the inner aspect of the follicle becomes level with the surface of the skin or projects above it, and still produces (but now from a larger area) its horny growth. Finally, the tendency to horny development extends from the follicle to the epidermis immediately surrounding it. These bodies absorb dirt, and consequently become more or less opaque and black. They are often shed, and then occasionally leave the surface from which they sprang tolerably healthy. Occasionally the disease is limited almost entirely to the sebaceous glands; and the surface of the trunk, and even the arms and legs, may be thickly studded with papules closely resembling those of *acne punctata*.

Although for descriptive purposes it may be desirable to divide ichthyosis, as has been above done, into two varieties, it must be borne in mind that there is no essential difference between them, and that not unfrequently patients whose general condition of skin is one of simple xeroderma present patches of greater or less extent, in which the corneous character is developed in the highest degree. It is desirable also to remark that, although in the general form of the disease the regions chiefly affected are those which have been pointed out, it occasionally happens that the hands and feet are much more seriously diseased than other parts. We have recently had a child under our care whose hands and wrists, feet and ankles, were covered, as with gloves, with horny growths varying from nearly an inch in length downwards.

*Treatment*.—The simple form of ichthyosis is incurable; but it may be much benefited and rendered tolerable by cleanliness, frequent baths, and keeping the surface anointed with oil or grease—olive oil, neat's-foot oil, and the like. The horny variety also is uninfluenced by medicine.

But it sometimes dies out in certain situations while it advances in others, and hence it is conceivable that it might occasionally subside altogether. But, although a cure is not to be expected, the horny growths may generally be removed, and the chief discomfort and offensiveness of the disease kept in abeyance, by the frequent use of warm baths, and application of poultices or oil.

## VII. LICHEN RUBER ET PLANUS

*Description.*—*Lichen ruber* is the name given by Hebra to an affection which is to some extent, no doubt, papular, but has no affinity whatever with the eruptions commonly included under the name of lichen. It begins with small colourless or reddish solid papules, for the most part unattended with itching. These increase in number, but very little in size, and presently coalesce at their margins so as to form smooth patches of uniform thickening and induration, the effect of which is to smooth away the finer furrows or creasings of the skin, to interfere with the free movement of parts, and to render the patient hidebound. The indurated skin is often thickened apparently to two or three times its normal thickness, and it loses its sensibility in a greater or less degree.

The disease begins symmetrically on different parts of the body, and may remain limited in its range, or may gradually spread over the whole surface. But there are certain situations in which its effects, however wide its distribution, are most obvious: these are the hands, feet, face,<sup>1</sup> and neck. The hands are affected mainly on their palmar aspects, but the convex surfaces of the metacarpo-phalangeal and phalangeal joints are also involved, and, in a less degree, the remainder of the backs of the fingers, which are apt to remain papular. The hands get stiff and almost useless, the fingers are kept widely separated and semiflexed, and cracks are apt to appear over the convexities of the joints. The feet and toes are similarly affected. The skin of the face becomes smooth and hard, the delicate wrinkles about the eyelids, forehead, and cheeks undergo more or less complete obliteration, and much of the patient's mobility of features and natural expression is lost. The primary papules and the infiltrated skin are said by Hebra to be red, and to have a tendency to yield thin scales. They are, however, sometimes pale, or of a pale dead-leaf colour, and free, or almost free, from desquamation. Hebra points out, also, that the nails get brittle, and either thin or thick; that the hair is unaffected; that the disease rarely undergoes amendment or cure; and that the patient tends to emaciate, and in the course of years to die from exhaustion. He further states that the papillæ of the skin have been found after death to be hypertrophied, and the root-sheaths of the hairs thickened.

<sup>1</sup> It is stated that the face never suffers. In Hebra's description, it is true, there is no express mention of the face, but he speaks of the disease as affecting the whole cutaneous surface. In the first case that ever came under our own care, and from which the description in the text is mainly drawn, the face was largely implicated.

The affection to which Erasmus Wilson gave the name *lichen planus* is now regarded by most dermatologists as being identical with Hebra's *l. ruber*. The original descriptions, however, scarcely agree; and typical examples of either condition are certainly met with. In *l. planus*, dusky-red papules appear irregularly over the surface, slowly increase in number, and thus tend to form irregular patches which often attain considerable dimensions. Not unfrequently, in the flexures of joints, for example, the papules fall into lines which correspond apparently with the folds of the skin.

The papules are flat, smooth and shiny, and irregularly quadrangular or polygonal, their form being determined by the arrangement of the natural creases of the skin. And thus, when they are close set, the affected area presents a tessellated aspect, and the skin appears much thickened. After a time the morbid surface is apt to become scaly, but no vesicles, pustules, or excoriations arise. The eruption is usually attended with much itching. The milder forms of the disease are fairly tractable. But occasionally it becomes general and inveterate; and the health suffers.

*Treatment*.—Arsenic in large doses, and cod-liver oil by inunction, or mild tar or zinc ointment, are the remedies which have been found chiefly beneficial.

---

### VIII. LICHEN SCROFULOSORUM

*Description*.—This affection was first described by Hebra. He observed it chiefly in males between the ages of 15 and 25. But it seems to occur equally in both sexes, and to be chiefly common in childhood, and for the most part in persons who are in a cachectic state and suffer from enlarged lymphatic glands, chronic bone-disease, or other conditions commonly termed scrofulous. The eruption is for the most part confined to the trunk, and is rarely seen on the limbs. It consists of miliary papules arranged in circular or oval groups. The papules are pale yellow, brownish-red, or of the colour of the skin, appear simultaneously, soon attain their full development, and never become vesicular or excoriate, but tend to yield a slight branny desquamation. The patches vary in size, slowly increase in number, and sometimes become very numerous. No itching or discomfort attends the eruption; and its discovery by the patient is often accidental. If left to itself the disease is of long duration; and its continuance is attended with the disappearance of old patches and the development of new ones. Moreover, it is apt to be complicated by the appearance of tubercles of acne.

*Treatment*.—Cod-liver oil and tonics appear to be the best internal remedies. And for local treatment Hebra recommends the inunction of cod-liver oil.

---

IX. ECZEMA (*Lichen. Strophulus*)

*Causation and description.*—The first of these affections is vesicular, that is, characterised by the development of vesicles upon an inflamed base; the second of them is generally regarded as papular—in other words, as due to the formation of solid pimples on an inflamed surface; the last is simply the lichen of children. Many modern authorities, however, now regard the various forms of eczema and lichen as merely varieties of the same disease, and strophulus *à fortiori* as a variety of eczema. We adopt this view, and combine them in a common description under the general name of eczema.

Eczema is an inflammation of the skin, for the most part much more acute in its phenomena than psoriasis, and attended with much more violent local irritation. It often commences with itching; but this is soon followed by the appearance of minute acuminate papules, which are more or less red from congestion, which may be either grouped in patches, or scattered, and which sometimes (but not by any means invariably) originate at the points from which hairs emerge. The papules gradually increase in size, sometimes retaining the solid form, sometimes being obviously vesicular almost from their first appearance. In the former case they may attain a line or more in diameter, when their acuminate character probably disappears; but more frequently perhaps they reach the average size of a millet-seed; and then, after they have remained out for a few days or a week or two, their redness fades, their surface desquamates, and they gradually subside. When the eruption is essentially vesicular, each papule (which is generally intensely inflamed) is occupied or crowned by a circumscribed accumulation of serum between the horny and the mucous layers of the epidermis. The vesicles are rarely larger than a poppy-seed, excepting when they are closely aggregated and neighbouring ones coalesce; under which circumstances a considerable area may get covered with a low undulating bleb, pinned down, as it were, here and there to the subjacent surface by the remains of the party-walls between adjoining vesicles. In this case, also, the eruption may subside at the end of a few days; but the appearances which attend its subsidence vary. Sometimes the contents of the vesicles become absorbed, and simple desquamation follows. More commonly the vesicles burst; and the exuded serum, mingling with the separating epidermis, coagulates into a scab, the character of which depends on a variety of circumstances—such as the part of the skin affected, the cessation or persistence of exudation, the entanglement in it of dirt or other foreign matters, and the admixture of blood or pus due to the effects of scratching or other local violence. In the simplest case the scab is often of a sulphur-yellow hue, and more or less powdery. More commonly perhaps it is of a dark colour, scaly or gummy, and adherent to the surface. On the scalp the crusts are apt to accumulate and to form thick dirty laminae.

Eczema is liable to become chronic. In some cases, especially in the papular form, the eruption then loses its vivid redness, and the surface gets

thickened, rough, scurfy, and fissured. In some cases, and mainly such as are vesicular, large tracts of skin become red, excoriated, and moist, and on close examination may be found to be covered in patches with a thin, opaque, soft, epidermic layer which is studded more or less abundantly, especially at the edges, with pits (very much like the perforations by which postage-stamps are separated from one another), at the bottom of which a red weeping surface is visible. These pits are excoriations, and correspond to vesicles; and in such cases are probably the only representatives of vesicles which can be recognised. Again, even in vesicular cases, the inflamed surface often after a time loses its vesicular character, becomes uniformly inflamed, brittle, and scaly, and assumes characters which, apart from the history of the case, are identical with those of chronic psoriasis or pityriasis rubra.

The vesicles or papules of eczema may be scattered and discrete, or collected into circular or oval groups of small size, or aggregated in larger irregular clusters, which tend to run together—the intervening skin being at the same time studded with isolated spots. In the first of these cases, the papular form of the disease constitutes *lichen simplex* or *strophulus intertinctus* (*red gown* or *red gum*); in the second, *lichen circumscriptus* or *strophulus volaticus*; and in the third, *lichen agrius*, or *strophulus confertus* (*rank red gum*). Eczema may be *acute* or *chronic*: the former lasting for a week or ten days, or more; the latter often consisting in successive outbreaks of the acute disease, but including those cases in which the skin assumes the features of psoriasis diffusa, and also the form commonly known as *eczema rubrum*. In the last there is general excoriation with intense redness, abundant exudation of serum, and the formation of numerous red oozing points in place of distinct vesicles. It is more frequently seen in typical completeness on the lower extremities of elderly persons.

No part of the surface of the body is free from liability to eczema. It attacks some parts preferentially, however, and then often receives a local epithet. Thus it frequently occurs upon the hairy scalp (*e. capitis*), constituting a very troublesome and chronic affection; on and in the ears (*e. aurium*); at the edges of the eyelids (*e. palpebrarum*); and on the cheeks (*e. faciei*). It is common in the axilla and bend of the elbow, about the anus, pubes, and outer part of the thigh, and in the bend of the knee. The nipples of suckling women and the umbilicus of the new-born babe are frequently affected. And it is not uncommon on and between the fingers. The affections known as *grocers' itch*, *bakers' itch*, and *ware-housemen's itch* are all of them eczema or *lichen agrius* of the backs of the hands and wrists.

Not unfrequently, when the eczematous inflammation is severe, spots of suppuration appear, intermingled with the original vesicles and papules; and the scales which result are thicker and darker than those of simple eczema. Eczema then approximates in its characters to impetigo, and is often termed *e. impetiginodes*.

Eczema, in its various forms, is the most common of all skin diseases.

It is frequent in babes and young children; but no period of life is exempt; and it may break out for the first time in extreme old age. It is not an unfrequent attendant on pregnancy and lactation. It is sometimes distinctly hereditary; and a previous attack generally predisposes to subsequent attacks. Its causes are not very obvious; occasionally, however, it is clearly produced by local irritation: in the head by the constant use of hard brushes; in the nipples by the irritation of sucking; between the thighs and buttocks and analogous parts by the effects of the local secretions and by attrition; and in bakers and others by the irritating substances among which they work. Eczema is also frequently induced by the presence of scabies or pediculi. These, however, are not the only causes. It is often idiopathic, and then not unfrequently preceded for a day or two by febrile symptoms. It is often ascribed to gout, dyspepsia, uterine complaints, teething, and the influence of weather and climate.

Excepting in the case of the extensive diffusion of the acute disease, eczema is rarely attended with constitutional symptoms. Locally it is characterised by the presence of itching, tingling, or burning. The itching in some cases, indeed, is unbearable.

*Treatment.*—There is no specific treatment for eczema. It is therefore especially important in every case to ascertain, if possible, the cause on which it depends, or whether or not the patient have any associated malady affecting the general health; and to treat it. Thus the constitutional treatment of eczema may resolve itself into the treatment of gout or indigestion; the local treatment into the destruction of insects, or the cessation from certain kinds of manual labour. Alkalies, such as liquor potassæ or the bicarbonate of potash or soda, in combination with vegetable tonics, are often resorted to. But the remedy on which most reliance is placed is arsenic. This is generally given in the same manner as in the treatment of psoriasis, and is by most physicians regarded as being most efficacious in the chronic forms of the disease. When febrile symptoms are present, mild laxatives and cooling medicines are desirable. Tonics are often beneficial in its later stages. It is well to pay attention to the diet. Alcoholic drinks are generally injurious, as also rich food and hot condiments. The local treatment must vary with the stage of the affection, its intensity, and extent. In the acute stage, and always when there is much inflammation, cold-water dressings or evaporating lotions, or even the cold douche, continued from ten minutes to half an hour at a time, is very useful. Under the same circumstances lead-wash and such-like applications are beneficial. At a later period, when there is much accumulation of scabs, it is important to remove them either by washing with soft soap and water, or by poulticing, or by the saturation of the part with olive oil. Then the surface must be kept clean; and mild mercurial ointments, or ointments containing lead or zinc, may be gently applied after each washing. In the dry and scaly condition of eczema which simulates psoriasis, the treatment applicable to the latter affection may be employed. Hebra recommends for some cases the rubbing in of

liquor potassæ until it acts chemically on the diseased structures, for the purpose both of removing the morbid surface and of promoting more healthy action. The caustic is applied once a week, the parts being treated with water-dressing in the intervals. Over limited area of disease, the application of the solid nitrate of silver sometimes effects a cure. As a rule, however, we think that soothing local treatment, combined with cleanliness, will be found most efficacious. And although soap may be occasionally employed to aid in the removal of scabs, persistence in its use is generally injurious. The patient should use, instead of it, bran, oatmeal, starch, milk, or yolk of egg.

---

### X. IMPETIGO (*Ecthyma*)

*Causation and description.*—The affections comprised under these names are essentially pustular; we regard them as identical, and shall describe them as varieties of impetigo.

Impetigo is a disease which consists in the formation of pustules at the surface of the skin, either between the cutis vera and epidermis, or between the corneous layer of the epidermis and the rete mucosum. The development of pustules is attended with more intense inflammation than that of vesicles or papules; and pustules are, for the most part, surrounded by well-marked congested areolæ, and situated upon more or less thickened bases. They occasionally commence in vesicles or papules; and thus eczema or lichen may pass into impetigo. Most commonly, however, they originate in spots of inflammation (stigmata, papules, or tubercles) in which suppuration is manifest almost from the beginning. Thus pustules vary in size from that of a pin's head (or less) to that of a split pea or bean. They are generally round or oval in outline, but sometimes irregular and angular, and project in the form of an oblate hemispheroid. At the end of a day or two they break, or their contents concrete, and scabs are formed, which are generally thicker and darker than those of eczema; but which, nevertheless, vary much in colour and consistence, being sometimes softish, translucent, and honey-like, sometimes dark, opaque, and tough. If the progress of the pustules be favourable, the scabs separate after a few days, leaving reddish spots behind them, which are soon effaced by the completion of a normal layer of epidermis. Very often, however, the scabs become detached while the subjacent surface is still secreting pus; and not unfrequently, when the scab seems fully formed, suppuration still goes on beneath and around it, leading on the one hand to a deeper erosion of the skin, on the other hand to the lateral extension of the pustule by the gradual undermining of the surrounding epidermis and the incorporation of the successive circles of suppuration thus formed. In the latter cases the local progress of the disease may be maintained for a long time; and in these alone, but rarely even here, is there danger of the production of permanent cicatrices. The long continuance of

impetigo sometimes leads to persistent harshness, muddiness, and deterioration of the skin.

The lymphatic glands in relation with the part affected by the disease generally get inflamed, large, and tender, and occasionally suppurate.

The pustules of impetigo sometimes come out singly (*i. sparsa*), sometimes in groups (*i. figurata*); and the groups may be of considerable extent. In the former case the pustules are generally larger than those of the grouped variety, and if the subjacent thickening and surrounding inflammation be considerable (as they are apt to be when the pustules are seated on the buttocks, or lower extremities, and in adults), the affection is often termed *ecthyma*. In the latter case the congestion connected with the several adjoining pustules blends, and thus forms a common area of inflammation which may be very intense (*i. erysipelatodes*). The scabs also, under such circumstances, are apt to run together and form a continuous mass or lamina (*i. scabida*).

Impetigo occurs on all parts of the surface. It is common on the head and face, especially of young children, and when abundant and confluent in the latter situation is sometimes called *porrigo larvalis*. Occasionally it attacks the hairy parts of a man's face, constituting one variety of the affection termed *syccosis*. It is then very intractable, owing probably to the root-sheaths of the hairs being specially involved. It is frequently met with about the buttocks, and indeed on all parts of the trunk and extremities.

Impetigo is liable to spread by inoculation: thus it may be conveyed from the child's head or face to the fingers with which it scratches itself; or from the nursing's face to the mother's bosom or hands; or, again, from child to child in families or schools. Sometimes it arises idiopathically, and is preceded by feverish symptoms, lasting for a day or two; it may be a subsequent development of lichen; and it is often produced by local irritation, due to pediculi, acari, and even mechanical causes. It is common during dentition. The duration of impetigo is very various, depending partly on the cause, partly on the health of the patient, and partly upon hygienic conditions. The acute form may subside at the end of a week or two; but the disease is very apt to become chronic, and to be kept up for months, and even years, by successive acute outbreaks. Those who have had previous attacks are liable to suffer from relapses. The constitutional symptoms are generally trivial; but there is often some degree of fever when the affection is extensive and acute, especially if the lymphatic glands are implicated. There is generally itching and tingling of the parts affected.

*Treatment.*—The local treatment of impetigo differs but little from that of eczema. In quite the early stage the application of cold or tepid water, or cooling lotions, is useful. When scabs have formed it is always important to effect their removal, and this may be accomplished in the same way as in eczema. After their removal, the use of lead or zinc lotions, combined with glycerine, or of mild mercurial ointments, is generally sufficient. Caustics are rarely beneficial, or even admissible.

When the hairy parts are affected it is well to have the hair cut short ; and in the case of sycosis it is generally necessary to resort to epilation. It is important to treat any associated malady under which the patient is labouring, and which may be affecting his general health. But as a rule tonics are indicated, especially iron, mineral acids, quinine and other vegetable bitters, and cod-liver oil. Change of air is often of great benefit.

---

## XI. SUDAMINA. MILIARIA

*Description.*—These names are employed to designate the minute vesicles which appear scattered over the surface of the chest, back, flanks, and sometimes upper arms and thighs of persons who are perspiring profusely, or more frequently perhaps of those who, having had a dry skin for some time, begin again to perspire. Thus we meet with them in rheumatism, pneumonia, and many fevers at the commencement of convalescence. They form at the orifices of the sweat-glands, and are due mainly to the imprisonment of minute drops of sweat by the horny layer of the cuticle. They are generally about as large as pins' heads, round or irregular in shape, containing a colourless acid fluid with leucocytes, and quite unattended with inflammation. They can be easily felt as small, prominent, hard bodies, but very often escape the eye unless carefully looked for, and then appear like minute drops of melted white wax. They end in branny desquamation. Occasionally their contents are opaline and of alkaline reaction, and each vesicle is surrounded by a narrow halo of congestion. It is to sudamina presenting these characters that the term *miliaria* is sometimes, but unnecessarily, applied. No treatment is required.

---

## XII. HERPES. PEMPHIGUS (*Pompholyx*)

*Causation and description.*—Herpes and pemphigus are vesicular or bullous affections, yet there is a close affinity between them and erythema, especially erythema multiforme ; and indeed it is questionable whether it might not have been best to discuss them all under the same heading. Both herpes and pemphigus become developed upon erythematous patches ; and not unfrequently these patches are papulate, discoid, circinate, gyrate, or marginate, and consequently the vesicular or bullous eruption assumes corresponding characters. Indeed, in no inconsiderable proportion of cases erythema, herpes, and pemphigus represent simply successive stages of the same affection. Various causes have been assigned for herpes and pemphigus, and among them one of great interest—namely, some affection, probably irritative, of the sensory nerves. One species of herpes (herpes zoster) is, as we shall presently

show, always limited to the area of distribution of some one or more of the nerves of common sensation, and usually attended with intense neuralgic pain; and, moreover, erythematous, vesicular, and bullous eruptions are shown by various authors, and especially by Charcot, to be common accompaniments of pachymeningitis of the cord and of other conditions causing equivalent irritative effects in the cord or nerves connected with it.

A. *Herpes*.—By this term we understand an affection characterised by the development of clustered vesicles, varying between the size of a small pin's head and that of a split pea, and seated on an erythematous base. A circumscribed area of redness, round, oval, or irregular in shape, first makes its appearance. This soon becomes thickly studded with papules, which speedily acquire a vesicular character, and in the course of twenty-four hours or less attain their full dimensions. The vesicles are close-set, and not unfrequently run more or less together, so as sometimes to form large bullæ. Their contents are in the first instance limpid and pale; but they often become dark from admixture with blood, or opaque and yellow in consequence of suppuration. After two or three days they dry up, and form thinnish dark-coloured or gummy scabs, which in a few days more become detached, leaving a whole but slightly reddened surface behind. There is always much heat and tingling or stinging during the earlier stages of the disease. Its total duration is rarely more than two or three weeks, and often considerably less.

Several forms of herpes are enumerated by dermatologists. We proceed to discuss the more important of them:—

1. *Zona* or *herpes zoster* (*shingles*).—This is the most important and striking affection of the group. It is characterised by the formation of clusters of vesicles on inflamed patches of various forms, and ranging from the size of the palm of the hand to that perhaps of a split pea. The clusters appear almost simultaneously, and irregularly scattered, over the area of distribution of one of the cutaneous sensory nerves. Hence they always occur within certain definite limits, and on one side of the body only. In addition to the general characters of herpetic affections, *zona* is apt to be attended with certain special peculiarities. Thus it is often associated with severe neuralgic pains in the neighbourhood of the part affected, which sometimes precede, sometimes accompany, and sometimes follow the cutaneous eruption, and often last for many weeks, occasionally for years; and again the inflammation is apt to be intense and to penetrate deeply, and hence to be slow of disappearance and to leave permanent scars, and sometimes (especially in the old and weakly) to become gangrenous.

The most frequent seat of *zona* is the chest or abdomen, where it takes the course of the cutaneous branches of one of the intercostal nerves. But it is not uncommon elsewhere, though it is very often then not recognised as *zona*. Von Baresprung enumerates nine varieties, and it would be possible, but is not necessary, to enlarge their number; they are as follows:—*z. facialis*, where the parts supplied by the fifth nerve

are affected, the surface of the conjunctiva being sometimes involved; *z. occipito-collaris*, following the distribution of the occipitalis minor, auricularis magnus, superficialis colli, and occipitalis major; *z. cervico-subclavicularis*, corresponding to the descending superficial branches of the cervical plexus (supra-sternal, supra-clavicular, and supra-acromian); *z. cervico-brachialis*, affecting surfaces supplied by branches of the brachial plexus—namely, the shoulder, upper-arm, fore-arm, and hand; *z. dorso-pectoralis*, corresponding to the third, fourth, fifth, sixth, and seventh dorsal nerves; *z. dorso-abdominalis*, corresponding to the eighth, ninth, tenth, eleventh, and twelfth dorsal nerves; *z. lumbo-inguinalis*, corresponding to the branches of the upper lumbar nerves, and extending from the loin to the linea alba, involving also the pubes and genital organs, the gluteal region and outer aspect of the thigh; *z. lumbo-femoralis*, corresponding to the cutaneous branches of the second, third, and fourth lumbar nerves, more especially the external cutaneous, genito-crural, and obturator, and affecting therefore mainly the anterior and lateral surfaces of the thigh and the inner aspect of the leg and foot; and lastly, *z. sacro-ischiatica*, which follows the cutaneous branches of the sacral plexus.

Zona attacks persons of all ages, but chiefly, it is said, young adults. It is held by some to be most common in spring and autumn, and also to occur only once in a lifetime. It is questionable, however, whether either of these statements be true. Its connection with nervous irritation has already been referred to; but nothing more in reference to its causation is known.

2. *Herpes simplex*.—This name may be conveniently used of those cases in which a group of vesicles or several such groups appear, so to speak, casually in some limited area, which then commonly gives a specific name to the affection. Thus we have *h. labialis*, affecting the lips and neighbouring parts; *h. palpebralis*, the eyelids; *h. auricularis*, the pinna of the ear; and *h. preputialis* and *puhendalis*, respectively the prepuce and the labia. In these cases the patches of disease are identical in appearance and progress with those of zona. But there is nothing to indicate that they have any connection with sensory nerves. Moreover, some of them (especially *h. labialis*) are very apt to attend an ordinary catarrh, and to come on in the course of acute pneumonia.

3. *Herpes iris* is the designation of an eruption of vesicles which arise in series of concentric rings upon a gradually enlarging erythematous disc. It is most frequently observed on the backs of the hands and wrists, feet and ankles, but is sometimes much more generally distributed.

4. *Herpes circinatus* is the name applied to an inflamed disc, which gradually increases in size, and whose enlargement is accompanied by the formation of a ring of vesicles at the circumference, while the centre for the most part gradually returns to a state of health.

It is obvious, as we have already pointed out, that there is no essential difference between the last two varieties or between them and erythema multiforme; and that *h. iris* and *h. circinatus* are simply

later phases of *e. iris* and *e. circinatum*. It may be added that intermediate papular conditions are sometimes observed, to which the names of *lichen iris* and *l. circinatus* might (unnecessarily indeed) be applied.

It is important, however, to bear in mind that the name 'herpes circinatus' is often given to the specific eruptions of favus and ringworm, and that the multiform erythematous and vesicular affections which have just been considered (though not themselves parasitic) are very apt to be simulated by and confounded with these vegetable parasitic diseases.

Lastly, cases are occasionally observed in which erythematous patches, irregular in form and size, appear almost simultaneously over the whole cutaneous surface, and become speedily covered with herpetic vesicles which tend to run together. The patches individually are like those of herpes zoster; and, moreover, like herpetic patches generally, run through all their stages in a week or two; but they differ from them in their wide distribution.

*Herpes iris*, *h. circinatus*, and the form of herpes last described resemble in their symptoms the corresponding forms of erythema multifforme. They are usually of trivial importance, but occasionally, when of extensive distribution, are attended with much febrile disturbance.

*B. Pemphigus*.—This term comprises most of the inflammatory affections of the skin attended with the formation of bullæ or blebs. These sometimes attain the size of a hen's or duck's egg, and are developed on round, oval, sinuous, or irregular surfaces. But associated with such blebs we often find single or grouped vesicles, no larger than those of herpes. Hence the blebs of pemphigus may be considered to vary between these limits. There is nothing specific, however, in the formation of a bleb; any patch of erythema or other forms of inflammation, or of gangrene, may become studded with vesicles, and any number of contiguous vesicles may run together and form a common cavity. It follows almost necessarily that there is nothing specific in the conditions to which the term pemphigus is applied, and that the limits between them and the affections receiving other names are to a great extent arbitrary.

Pemphigus is not unfrequently (as has been pointed out above) the fully developed stage of *herpes iris*, *h. circinatus*, and other forms of generally distributed herpes. The stages of the disease are then well marked: the first being the appearance of a disc, ring, or irregular patch of erythema; the second, the formation of small vesicles, sometimes in a ring at the circumference, sometimes in the centre, sometimes generally over the surface; and the third, the extension or blending of these vesicles and the evolution of a prominent bulla, the edge of which becomes, for the most part, conterminous with that of the erythematous redness. Owing to the coalescence of neighbouring patches of erythema, neighbouring bullæ may coalesce into sinuous or gyrate bullous bands several inches in length. Further, the eruption may be sparse or limited in extent, or it may be general and abundant. The full development of the disease may occupy three or four days, or more, but is often much more rapid. In cases of this kind it sometimes happens that extensive tracts

of surface become erythematous and remain so for some considerable time, vesicles and bullæ from time to time appearing here and there upon them. In other cases of pemphigus, the formation of bullæ is almost coetaneous with the appearance of the erythema, which may then indeed escape recognition as a separate stage of the affection, both generally being preceded by violent itching, stinging, or burning. The bullæ of pemphigus are generally plump and distended with a pale straw-coloured serum, which, after a while, gets darker in tint, or milky and opalescent. After a few days the contents begin to disappear by evaporation or absorption, or the bullæ rupture and they escape. Then a thin dry pellicle, consisting of the epidermis which has been raised up and of coagulated exudation, forms upon the affected surface, and after a few days more becomes detached, leaving a sound but somewhat reddened area behind. Sometimes, especially if the part have been irritated by scratching or otherwise, or if the general health of the patient be bad, the scab more resembles that of eczema or impetigo, probably re-forms after removal, and convalescence may be much protracted. Ulceration or even gangrene may ensue.

As will be gathered from the foregoing account, pemphigus presents a good many varieties. Sometimes it is *acute*, its entire duration being comprised within a period of three or four weeks. More frequently it is *chronic* (chronic, however, in the sense in which urticaria evanida is chronic), that is prolonged by successive acute attacks, and may thus be continued for many years. It is then often termed *p. vulgaris*. Sometimes a single bulla breaks out suddenly, to be followed on its subsidence by a second, and then by a third, and so on (*p. solitarius*). A form of the disease, termed *p. infantilis*, is occasionally met with in new-born children; large bullæ form on the neck, behind the ears, on the buttocks, genitals, wrists, and other parts, and for the most part progress unfavourably, ending in suppuration, ulceration, and gangrene. A further variety is that called by Alibert *p. foliaceus*. It is characterised by the successive formation of bullæ of small size, which are generally flat and flaccid, and the contents of which become more or less distinctly purulent, and dry up into thick yellow flaky scabs. These on separation leave a deeply congested weeping surface. *P. foliaceus* is said to spread gradually until it occupies the entire surface of the body, and never to be cured.

The causes of pemphigus are not clearly known. There is reason, however, to believe that in some cases, especially in that of *p. infantilis* or when it occurs on the soles or palms, the origin is syphilitic. It not infrequently arises in persons suffering from mental worry or distress, or who are in feeble bodily health. And, as we have already pointed out, it appears in some instances to be connected with affections of the spinal cord or sensory nerves. The symptoms which attend its progress vary. There is often some degree of fever—sometimes high fever, the temperature reaching  $104^{\circ}$  or  $105^{\circ}$ ; and, when the affection is much prolonged, debility and emaciation may ensue. This latter is especially the case in the foliaceous form. New-born children affected with pemphigus

generally succumb speedily. In many cases the patient's health remains apparently unimpaired throughout the whole course of the malady.

*Treatment.*—Whatever its form may be, herpes seldom requires special treatment. Cooling lotions, simple ointments, and protection of the affected parts against rubbing, include all the local measures that are usually necessary. The only important object to aim at in the treatment of zona is the relief of the severe neuralgic pain which is so often associated with it. For this various measures may be tried, such as the local application of blisters or other counter-irritants, the inunction of belladonna, or of aconitia ointment, and the use of leeches; and, besides these, morphia or other sedatives administered by the mouth or hypodermically.

The bullæ of pemphigus require little local treatment. They may be punctured and their contents permitted to escape; but it is inadvisable to allow the cuticular pellicles covering them to get detached. For this reason, among others, it may be necessary to protect the parts with simple ointments spread on lint. For internal treatment iodide of potassium and mercurial preparations should be employed when syphilis is suspected. Arsenic is much lauded by some. In most cases, however, tonics are sooner or later indicated.

### XIII. RUPIA

*Causation and description.*—Rupia is described as beginning with flat bullæ, rarely, if ever, exceeding half an inch in diameter; first containing clear serum, then producing very thick greenish-brown or dark-coloured scabs and deep destructive ulceration. In some respects, therefore, the disease resembles pemphigus; but it differs from all ordinary forms of pemphigus in the fact that its bullæ are the result, not of superficial, but of deep-seated disease. Rupia, indeed, is to be distinguished less by the occurrence of bullæ than by the character of its post-bullous stages. The rupial bulla slowly increases in size, is surrounded by a halo of congestion, and seated on a slightly thickened base. A scab soon forms, but while it is forming the bulla spreads at its margin, and fresh matter, which also soon coagulates, is produced around and under the first-formed scab. In this way the rupial sore increases in diameter, the scab increases in thickness and prominence, and the subjacent ulcer becomes deeper and deeper. The resulting scab is always very thick, but sometimes flat and flaky, something like an oyster-shell (*r. simplex*), sometimes conical, like a limpet-shell (*r. prominens*), sometimes irregular and rocky in shape. On its removal, a fresh scab usually forms. Rupial ulcers are always deep and unhealthy-looking, and cause much destruction of tissue, and permanent cicatrices. In some cases, and especially in children, the ulceration extends rapidly, assuming a phagedænic character (*r. escharotica*), or becoming distinctly gangrenous, when it is sometimes

termed *peniphigus gangrenosus*. Rupial sores are generally scattered and few in number, and are not limited to any particular part of the person. They are, perhaps, most common on the buttocks and lower extremities.

Rupia occurs rarely, if ever, in persons who are not obviously weakly and cachectic, and most frequently in those who have previously had syphilis. Indeed, there is some reason for regarding true rupia as essentially a syphilitic disease.

*Treatment*.—In the constitutional treatment of rupia, tonics of various kinds, iron, mineral acids, vegetable bitters, cod-liver oil, together with good diet and change of air, are all important. Anti-venereal remedies must not, however, be forgotten, especially if there be a clear syphilitic history. For local treatment, poultices are necessary to aid in the detachment of the scabs; and the resulting ulcers must be treated not only with poultices but with stimulating or detergent ointments or washes, and even in some cases with undiluted caustics, such as nitrate of silver, nitric acid, acid nitrate of mercury, or other such agents.

#### XIV. STEARRHŒA. ACNE

*Causation and description*.—By *acne* is meant an inflammatory affection of the sebaceous glands, dependent on, or at all events connected with, retention of their secretory products. In most inflammations of the skin the sebaceous glands of the parts affected share in the inflammation; and always in *acne* there is more or less tendency for inflammation to extend from them to the contiguous structures. Hence, as might be supposed, *acne* occasionally (and especially in some of its forms) passes into other recognised varieties of inflammation of the skin. Further, inflammation of the sebaceous glands is sometimes attended, not with retention of secretion, but with increased production and flow, so that we may have an inflammation of them which is not *acne*. This is sometimes named *stearrhœa*.

A. *Stearrhœa*. The secretion of sebum in some persons is naturally exceedingly profuse, but it is not therefore morbid, and becomes seriously inconvenient only in the absence of scrupulous personal cleanliness. In some cases, however, an excessive production of sebum occurs over certain limited areas, attended with distinct hyperæmia of the parts, and more or less obvious hypertrophy of the glands. The increased production is limited in fact to patches of distinct erythema. This affection is not unfrequent in the scalp and on the face, especially in children. The secretion is usually more solid than sebum should be, and with the superficial epidermis concretes into greasy flakes, which adhere to the surface. A condition is thus produced which differs little, and not essentially, from pityriasis of the same parts. More rarely the secretion is quite fluid, and may be seen, after cleansing the surface, to form a minute drop at

each glandular orifice. This condition, which is occasionally observed on the cheek and nose, is apt to be chronic, and sometimes becomes permanent.

B. *Acne*.—The unnatural accumulation of sebaceous matter in the sebaceous glands is extremely common. It may be met with in glands which are still patent, as well as in those whose mouths are obliterated. In the former case the orifices are dilated and prominent, and occupied by the dirt-blackened superficial portions of the accumulated sebum, the whole of which may, by squeezing, be removed in the form of small, maggot-like bodies (*comedones*). In the latter case no orifices generally are detectable, the sebum retains its normal yellowish hue, and concretes into hard, pearly, laminated masses. This condition was termed by Willan *strophulus albidus*. A small incision is generally necessary for their removal. *Sebaceous tumours* or *wens* differ little, except in size and the consistence of their contents, from the bodies last named.

When such accumulations of sebum are associated with inflammation of the parts immediately surrounding them, we have that condition present to which the term *acne* is generally applied. *Acne*, therefore, may occur in two forms. In the one there is circumscribed inflammation, attended with induration, prominence, and duskiness of tint, but the cause of inflammation is rendered obvious by the fact that at the most prominent part of the tubercle there is a dilated sebaceous orifice, choked with the secretion of the gland. In the other form the orifice of the gland is undistinguishable, the accumulation is deep-seated, inflammatory products are diffused around, beneath, and superficial to it, and thus an indurated congested prominent tubercle is produced, which yields on inspection no visible proof of its connection with sebaceous accumulation. The tubercles of *acne* vary in size, and are sometimes as large as a horse-bean. They often suppurate, but, especially in the latter form, suppurate very slowly, leading before they discharge their contents to a good deal of localised disorganisation, and eventually to the production of permanent scars. Their contents are scanty but thick, and consist partly of sebaceous matter, partly of pus.

Different forms of *acne* are described, of which the majority are mere varieties of the same condition, and are generally combined in various proportions in the same case. The term *a. punctata* is often applied to that very common condition in which the sebum simply accumulates in the follicles, and leads by its accumulation to the production of a series of black-tipped papules. By *a. simplex* is generally understood *a. punctata* associated with inflammation and suppuration; the papules being surrounded by congestion, and often going on to the formation of small superficial abscesses, which in a short time discharge their contents, and then after a few days, or a week or two, heal up. The name *a. indurata* is given to those cases which are marked by general enlargement and induration with dusky or livid discoloration, and slow, deep-seated suppuration. One form of *sycosis* is distinctly *a. indurata* of the hairy regions of the face.

Any part in which sebaceous glands exist may be the seat of acne. But it is most common on the face, especially the forehead, cheeks, nose, and chin; and on the trunk, mainly between the shoulders and on the chest. It rarely occurs in young children, excepting in the form of *strophulus albidus*. It is most common in both sexes about the period of puberty, and from that time onwards to two or three-and-twenty. It is frequently met with, however, and then especially in its indurated form, in persons of middle and even advanced age. The causes of acne are obscure. It is certain, however, that the tendency to it runs in families, and that it has a special connection with the period of development and maturation of the sexual functions.

C. *Acne rosacea*.—The condition to which this name is commonly given has been regarded by most modern writers as a mere variety of acne. Hebra, however, maintains that it is essentially distinct from acne, although frequently associated with it. It generally consists in more or less extensive patches of inflammatory redness, associated with slight infiltration of the affected cutis and visible dilatation of the superficial vessels, and also with the presence here and there upon the inflamed patches and in their neighbourhood of tubercles corresponding precisely to the description already given of those of acne indurata. The affection is really therefore an inflammatory condition of certain parts of the skin, in which there is a special tendency for the sebaceous glands to be implicated. Acne rosacea is limited to the face, affecting sometimes the nose, sometimes the cheeks, sometimes the forehead, sometimes the chin, but generally several of these regions at the same time. It is for the most part symmetrical in its distribution, and tends gradually to extend. It usually begins with circumscribed hyperæmia of the nose or cheeks, often attended with an increased secretion of sebaceous matter, and generally with a more or less obvious development of dusky red tubercles, which may or may not suppurate. This condition, variable at first, soon becomes permanent, the cutis getting infiltrated and thickened, the small veins of the part dilated and tortuous, the tubercles more abundant and larger, and the face consequently much disfigured. In this latter state the disease may remain for many years, or for life, without material change. But in some cases, and more especially in elderly men who have been addicted to alcoholic excess, the affection, which is then almost invariably limited to the nose and its immediate neighbourhood, assumes a hypertrophic character; the parts which were originally affected with a simple form of acne rosacea become swollen and tuberculated, until in some instances the nose forms a huge misshapen, lobulated, pendulous mass. These changes are due to inflammatory hyperplasia of the cutis vera, the tissues subjacent to it being rarely, if ever, implicated. The sebaceous glands, however, are involved and hypertrophied, sometimes still discharging their products through the yet patent ducts, sometimes from obstruction allowing accumulation of sebum, and perhaps undergoing suppuration. The affected parts become deeply congested, and the dilated varicose veins larger and more numerous.

Beyond heat and flushing, which are liable to frequent exacerbations, little local inconvenience or discomfort attends acne rosacea in any of its forms.

Acne rosacea, in its simpler variety, is an affection of adult life, coming on generally between 25 and 30, but sometimes making its appearance for the first time after the age of 10. It is far more common in women than in men. The hypertrophic variety of the disease, on the other hand, is rarely observed in women; and it attacks the opposite sex for the most part in middle age or the decline of life. The causes of hypertrophic acne rosacea are not in all cases obvious; there is no doubt, however, that in large proportion it is traceable to long-continued habits of intemperance, or over-indulgence in spirituous liquors. The difficulty of assigning a cause to the other form of this affection is still greater; nevertheless, it is certain that many of those who suffer from it are dyspeptic or liable to uterine disturbances, and that when any of these complications are temporarily present there almost invariably occurs marked exacerbation of the facial inflammation.

*Treatment.*—In steorrhœa plentiful ablution with soap and water, and the use of astringent lotions, containing acetate of lead or sulphate of zinc, or of mercurial preparations, are the chief measures to be employed. Constitutional treatment is generally useless.

In treating acne it is of great importance to insist on frequent and thorough washing with soap and warm water, to be followed by the friction of a rough soft towel, or flesh-brush. These measures, however, are even more important to prevent than to cure. All black spots should be removed, either by squeezing the papules in which they are contained between the nails, or by pressing down upon them a ring a little larger than the black spot, and including it. The mouth of a watch-key answers the purpose very well. Superficial collections of matter should be punctured and discharged. The chronic tubercles of acne indurata should be opened with a narrow-bladed knife, and have their contents expressed, or should be touched at the summit with the acid nitrate of mercury, or some other equivalent escharotic. The local inflammation may be allayed to some extent by the use of lead-wash, or a lotion containing from two to four grains of sulphate of zinc, or from half a grain to two, three, or even four grains of bichloride of mercury to the ounce. Mild mercurial ointments are sometimes useful. Sulphur, in the form of ointment or lotion, is strongly recommended by most dermatologists. Beyond local treatment we can aim only at improving the general health, and must be guided, therefore, solely by the general symptoms which the patient presents.

In sycosis it is important to have the hair of the affected parts kept closely cut, and to remove the hairs running through the tubercles or pustules by frequently repeated epilation. Hebra insists on the necessity for keeping the surface constantly shorn, for the application of sulphur and other stimulating ointments, and for the incision of the inflamed tubercles.

The treatment of acne rosacea differs little from that of simple acne.

But it is especially important here to attend to the general health and habits of the patient, to remedy indigestion, to remove anæmia, to prescribe a wholesome unstimulating diet, and to maintain the healthy functions of the skin and other organs. The local treatment is absolutely that of acne simplex; but it generally needs more persistent employment.

## XV. KELOID (*Kelis*)

*Causation and description.*—This affection was first described and named by Alibert. It is characterised by the gradual formation of roundish, elongated, linear, branching, or reticulate patches, which are elevated a line or two, or even more than that, above the general surface, and appear to be mainly a hypertrophic condition of the cutis. The patches vary in colour, but are usually either white and shining, or of a more or less rosy hue, and are often marked with vascular ramifications. They present for the most part a smooth and rounded surface, and generally send out here and there claw-like processes or spurs which gradually lose themselves in the surrounding healthy skin. It is from this peculiarity that their name was derived, and that they acquire their generally recognised resemblance to hypertrophic scars. They are dense and firm in consistence, and never become covered with scales or crusts, or undergo ulceration or other such destructive changes. They are sometimes attended with tingling, itching, or burning, and are often tender to pressure. Their progress is slow; they usually extend gradually for a time, and then become stationary; occasionally they undergo involution, and disappear. In the early stage of their development they consist largely of fusiform cells, and are by Virchow and others regarded as sarcomatous; at a later stage they become almost entirely fibrous.

Keloid commonly occurs in isolated patches of various sizes on the chest or back; but it may be multiple, and may be met with on any part of the surface, even the face, ears, genital organs, and extremities. Occasionally it involves nearly the whole of the trunk.

The causes of the disease have not been clearly determined. It occurs, however, mainly in adults, and seems not unfrequently to be induced by local irritation or injury. Indeed, one form of it, generally termed *false keloid*, is clearly due to hypertrophic changes occurring in connection with ordinary scars. A remarkable case<sup>1</sup> in which the face became affected to an extreme degree after small-pox has been recorded by Dr. Goodhart.

The *treatment* of the disease is unsatisfactory. The growths, when large, have occasionally been removed with the knife, but the results have not been encouraging. Local applications, such as iodine paint, blistering fluid, and various forms of stimulating ointments, have been tried and recommended; but, again, the benefit resulting from them has rarely been very decided.

<sup>1</sup> 'Path. Trans.' vol. xxxi.

XVI. XANTHOMA (*Vitiligoidea. Xanthelasma*)

*Causation and description.*—This affection was first clearly described by Drs. Addison and Gull under the second of the names given above. It has since been carefully investigated and described by various dermatologists, and more especially by Dr. Hilton Fagge. It consists mainly in a kind of fatty or atheromatous change in the texture of certain portions of the skin, and in this respect has a very close affinity to atheroma of the arteries. The affected parts appear on section to consist of fibrous tissue (mainly the normal fibrous tissue of the part) studded more or less abundantly with groups of oil-globules. It occurs in two forms, namely *x. planum* and *x. tuberosum*. In the former, the affected portions of skin present an opaque, yellow, or buff colour, are distinctly margined, and, although perhaps appearing to be elevated, are actually level with the general surface and undistinguishable from it in consistence and feel. In the latter variety, papules or tubera arise, varying from the size of a pin's head to that of a hazel nut, which sometimes by their aggregation form nodulated masses of considerable extent. These are generally yielding, elastic, and but little indurated, are of the normal colour of the skin or of a reddish hue, and frequently studded, especially in their more prominent parts, with opaque yellow spots. Xanthoma is often unattended with local uneasiness; in the tubercular form, however, there is not unfrequently some degree of itching or tingling, and tenderness. Its course is for the most part progressive; but sometimes it becomes stationary and occasionally disappears. It never undergoes ulceration or other such destructive changes.

Xanthoma may occur on almost any part of the surface; on the eyelids, nose, ears, cheeks, neck, head, shoulders, nates, back of elbows, and front of knees, about the wrists and ankles, on the palms and soles, and on the knuckles of the fingers and toes. When occurring in the neighbourhood of joints it seems to be connected with the tendons. It has also been observed in the mucous membrane of the nose, gums, lips, tongue, and larynx. The plane form of the disease is met with mainly in connection with the eyelids, ears, and other parts of the face, and with the mucous membranes. This, if the affection be at all largely distributed, occurs concurrently with the tuberos form; but it is not unfrequently alone present, and limited to the face, and more particularly to the eyelids. In the latter case it usually commences in the skin of the upper lid near the internal canthus, and may gradually extend thence until it involves the greater part of both lids. It is occasionally seen in the neck, flexures of joints, and especially on the palmar surface of the hands and fingers, feet and toes, to extend along the deeper creases, and mainly in the form of two narrow parallel bands, one on either side. The tuberos form may be met with in the same situations as the other, but is most commonly observed upon the extremities. When occurring in the palms or soles, the tubercles are usually of small size, but very numerous, and give a mottled

aspect to the affected surface ; and on the wrists and ankles the affection may assume a good deal of the typical appearance of keloid.

Although the causes of xanthoma, like those of so many other affections, are obscure, some curious facts have been observed which seem to have some relation with its etiology. Many recorded cases, probably half, have laboured during the development of the disease under jaundice, due to organic disease of the liver ; and many also, as Mr. Hutchinson has pointed out, appear to have suffered from sick headache. In the very few published cases in which the disease appeared in a tubercular form on the palms and soles, the patients were suffering at the time from diabetes ; and, moreover, the eruption got well eventually, or underwent considerable improvement. It is mainly an affection of adult life, and attacks men and women equally. It occasionally appears in infancy, and may be congenital ; and in such cases is apt to affect several members of a family.

*Treatment.*—No efficacious treatment is known.

## XVII. SCLERODERMIA (*Scleriosis. Addison's keloid. Morphew*)

*Causation and description.*—Under the above series of designations have been described a number of morbid conditions of the skin, which are now generally admitted to be closely correlated, if not absolutely identical with one another. They are very rare, and consequently, although interesting, do not claim any lengthened consideration.

They are all characterised by the appearance of patches of induration and thickening ; which vary in extent and shape ; tend gradually to increase in size ; are attended often with tingling, sometimes with anæsthesia ; are white and ivory-like, or of a pale yellowish or brown hue, sometimes mottled, sometimes surrounded by a halo of congestion or discoloration ; are for the most part of long duration, and in their progress apt to become faintly tubercular, or to desquamate, or even to ulcerate, and, when they finally disappear, to leave behind them more or less brownish discoloration, with atrophy and cicatricial scarring of the surface. The affected parts are for the most part smooth, scarcely, if at all, elevated above the general level, and incapable of being pinched up in a fold ; and the thickening, although generally limited to the skin, sometimes involves also the subjacent connective tissue. The affection appears to consist anatomically in an overgrowth of dense connective tissue, associated with the accumulation of cells, resembling lymph-cells, in the sheaths of the small vessels.

A. It is comparatively not uncommon to meet with a patch or group of patches of sclerodermia on one side of the forehead, in the area of distribution of the fifth pair. The affection then usually remains limited to this region. It commences insidiously, perhaps as a mere discoloration, gradually increases in size, and occasionally spreads to the hairy

scalp, where it causes circumscribed alopecia. It is very chronic in its progress.

B. Another variety of the affection, Dr. Fagge's 'circumscribed scleriasis' (scleroma), is that which Dr. Addison described under the name of 'true keloid,' deriving the word keloid from *κηλιδ* (a spot produced, as it were, by burning). In this, which is also a very chronic affection, the patches commence variously, sometimes as a mere loss or change of colour, sometimes as a mere depressed smoothness, sometimes as a simple induration, attended or unattended with itching or tingling. The patches differ in shape: are round, oval, band-like, irregularly polygonal or stellate, and not unfrequently send out promontories, as it were, or peninsulas, into the surrounding healthy skin. They vary also in size: are sometimes no larger than a sixpenny-piece or shilling, but tend to increase, and thus sometimes involve ultimately very extensive areas. They are usually multiple, and new spots are apt to arise from time to time. Beyond the itching and tingling, the main source of discomfort to the patient is the interference with the free use of parts which any considerable extension of the disease involves. He becomes hidebound, and his fingers, hands, arms, or other parts which are affected, grow more or less distorted, fixed, and useless. This immobility is increased when (as often happens) the skin becomes adherent to the subjacent tissues, and when (as also occasionally takes place) subjacent muscles waste. The mucous membrane of the tongue, lips, and gums is sometimes involved in the disease.

C. A third form of the disease, which Dr. Fagge designates 'diffused scleriasis' (scleroma), is that to which the names 'sclerema,' 'scleroma,' 'scleriasis,' and the like, are more particularly given. It appears to have been observed almost exclusively on the Continent, and is mainly characterised by the rapid extension of scleroderma over large parts of the surface of the body. It seems frequently to have begun at the back of the neck, and thence to have spread to the face, back and front of the trunk, arms, and even over the whole surface. The tongue may be involved. The integument becomes thick, hard, ivory-like, and smooth, the arms, hands, and fingers stiff and immovable, the face an expressionless mask. The aspect and feel of the affected regions have been likened to those of a frozen corpse.

None of the above varieties of scleroderma appears to be associated with any indications of constitutional suffering; and the secretion from the kidneys and even that from the affected portions of the skin remain normal. They are all more or less chronic in their course: the first two lasting, as a rule, for years, and leaving on their subsidence marked signs of their pre-existence behind; the last, however, often disappearing entirely in the course of a few months. Women appear to suffer much more frequently than men. In some cases (especially of the diffused form), the attack is said to have originated in exposure to cold or wet; but little or nothing further is known with respect to the causation of the disease. There is some obvious resemblance between scleroderma and

the later stages of lichen ruber, and still more between it and true leprosy, of which disease some authors regard its circumscribed forms as mere varieties.

*Treatment.*—No local measures seem to have been useful in the treatment of scleroderma. The constitutional remedies which have been employed include cod-liver oil, quinine, iron, arsenic, and iodide of potassium.

## XVIII. ELEPHANTIASIS (*Elephas. Pachydermia.*

*Barbadoes Leg. E. Arabum*)

*Causation and description.*—The condition to which the above names have generally been given is mainly a disease of tropical climates, and more especially of certain parts of India. Its chief characteristic is hypertrophy of the connective tissue of certain parts of the body, associated with early implication of the lymphatic glands and vessels.

A. *Elephantiasis* commences with an erysipelatoid inflammation of the part about to become permanently affected, attended with febrile symptoms, and indicated by superficial redness, and general and deep infiltration. At the same time the superficial veins and lymphatics generally form red painful indurated cords, and the corresponding lymphatic glands undergo considerable acute tumefaction. If an incision be made at this time, a large quantity of yellowish transparent fluid, coagulating spontaneously, and having all the characters of lymph, escapes. After a few days, probably, the inflammation subsides, but more or less swelling remains. Subsequent attacks of inflammation, excited by various causes, supervene at irregular intervals—each attack adding to the mischief, and leaving behind it a tendency to still further hypertrophic change. The final result is that the affected part becomes largely, sometimes enormously, increased in bulk, and altered in aspect.

In some cases the hypertrophic condition occupies mainly the skin and subcutaneous connective tissue; in some it involves the whole of the connective tissue between the skin and bone. In either case, but chiefly in the former, the skin is liable to be much modified in texture and form; sometimes it becomes coarsely papular or warty, sometimes studded with nodular elevations, sometimes undergoes ulceration; and the epidermis, though often remaining normal, may desquamate, or get thick or horny, or acquire the characters observed in ichthyosis, or become more or less deeply coloured from deposit of pigment-granules in the rete mucosum. The affected surface, moreover, may be anæmic, congested, or livid. When the disease extends deeply, fat, muscles, and nerves get compressed and waste, but the bones undergo hypertrophy—new layers and irregular outgrowths forming, by means of which adjoining bones occasionally become organically united.

Elephantiasis appears to consist primarily in an inflammatory hyperplasia of the cellular elements of the connective tissue, in connection with which (according to Virchow) there is reason to believe that the roots of the lymphatic vessels are specially involved. Inflammatory overgrowth of the elements of the lymphatic glands next ensues, with obstruction to the passage of lymph through them. Then this fluid stagnates in the lymphatic vessels, which sometimes dilate even to their radicles in the cutaneous papillæ; and it presently accumulates in the interstices of the affected tissues, adding to their bulk and at the same time stimulating them to overgrowth. It is only in the early stage of the disease that the dilated condition of the lymphatics admits of ready detection. At a late period the morbid tissues are characterised mainly by the presence of a dense accumulation of white fibrous tissue. The lymphatic glands also, after a time, become the seat of fibroid change.

The regions most frequently attacked with elephantiasis are the lower extremities and genital organs. But other parts may become affected, and especially the female breast. In the first of these cases the disease may commence in the toes or about the ankle, and gradually involve the whole leg up to the knee. It rarely, however, rises above that point. In extreme cases the form and appearance of the affected member remind one of those of an elephant's leg, whence the common name of the disease. When the scrotum or labia are involved they often reach enormous dimensions; the scrotum, which is sometimes also the seat of hydrocele, may attain a weight of 50 or even 100 lbs.

Elephantiasis is a disease mainly of adult life, and is more common in men than women. Its progress is slow, but is largely governed by the conditions under which the patient lives, or the care he takes of himself. Fatigue and exposure to weather, or of the affected part to anything provocative of irritation or inflammation, are apt to aggravate it; while, under opposite conditions, the disease may make but little progress, or remain stationary. There is nothing in it necessarily inimical to life; but want of cleanliness or other accidental circumstances may give rise to ulceration or gangrene, and thus imperil life or cut it short.

Elephantiasis does not appear to be a specific disease. Swellings and indurations of precisely the same kind are apt to occur in the vicinity of old ulcers, and especially in parts which have undergone repeated attacks of erysipelatous inflammation. Only in these cases the hypertrophy rarely, if ever, goes on to that inordinate extent which characterises the endemic elephantiasis of tropical countries.

B. *Elephantiasis lymphangiectodes*.—A condition, closely related to elephantiasis, if not identical with it, occasionally arises independently of inflammation, at all events of inflammation of the parts chiefly implicated. It is due sometimes to the continued application of a tight ligature round the upper part of one of the extremities, sometimes to obstructive disease in the lymphatic glands or lymphatic vessels, either arising during adult life, or of congenital or infantile origin. In all of these cases the morbid condition appears to be chiefly, if not wholly, due

to obstruction of lymphatics, with consequent dilatation of those below the seat of obstruction, accumulation of lymph in the textures, and overgrowth of the connective and other tissues. The lesions closely resemble those of elephantiasis Arabum; and the resemblance is not unfrequently enhanced by the occasional supervention of attacks of inflammation. The disease appears to be not uncommon in tropical climates; and is attributed by Dr. Lewis to the presence of filariæ, and to obstruction of the lymphatics by these entozoa.

This form of elephantiasis generally first reveals itself by simple increase in bulk of the part affected. This increase goes on more or less insidiously, until it becomes considerable: the tissues getting indurated and dense, and the surface pale, congested, or otherwise modified in colour, and either smooth, papular, or tuberculated. After a time groups of vesicles make their appearance, sometimes widely distributed, sometimes in an irregular patch, sometimes in a linear series, and generally embedded, as it were, in the solid tissue. These, which are really dilated lymphatic spaces, are apt to rupture from time to time, and then to exude considerable quantities (sometimes several pints) of lymph, which coagulates after its escape, and is either yellowish and transparent, or milky from the presence of molecular fat. Sometimes similar groups of vesicles appear on areas of apparently otherwise healthy skin, and independently of hypertrophy or overgrowth of connective tissue. This affection is usually limited to one of the lower extremities, or to the upper part of the thigh and contiguous part of the abdomen, or to the genital organs and perinæum; and it may be added that there is good reason to believe (as is elsewhere pointed out) that chyluria is due to a similar condition involving the mucous membrane of the bladder or other parts of the urinary tract. When the lower extremity becomes affected in infancy, not only does the limb increase generally in bulk, but the bones, relatively to those of the opposite member, become manifestly hypertrophied—augmented both in thickness and in length.

*Treatment.*—The treatment of elephantiasis should be mainly prophylactic; the patient who is suffering from it should be careful to avoid all causes of renewed inflammation; he should keep the affected parts clean and cool, should not expose himself to cold or vicissitudes of temperature, and should avoid all over-fatigue and exposure of the parts to irritation or injury. Moreover, these should not be allowed to be pendulous. During the inflammatory stage antiphlogistic remedies may be had recourse to; fomentations or cold lotions should be applied locally, with the object of preventing hypertrophy, and it may be of promoting absorption; and the affected region should (if its form or position permit) be kept evenly and firmly bandaged. Hebra recommends that the bandage be of cotton, and dipped in water at the time of application. He further recommends that, previous to the use of bandages, scales and crusts be removed by cataplasms, baths, or greasy applications, and that afterwards mercurial ointment be rubbed in.

## XIX. MOLLUSCUM CONTAGIOSUM

*Causation and description.*—This is an affection occurring mainly among children, and characterised by the development of small globular or sub-globular outgrowths from the skin, usually varying from the size of a pea downwards, but occasionally attaining larger dimensions. They are sessile, though sometimes attached by constricted bases. They differ little if at all in colour from the surrounding skin, but have a slight degree of translucency. They are unattended with pain or itching. Each tumour for the most part presents a distinct central depression, from which can often be expressed a little milky fluid or wax-like substance. On section it is found to consist of a lobulated gland-like body, the crypts of which are lined with columnar epithelium, and filled with rounded cells of large size. All these crypts communicate with a central duct, which for the most part is full of cells containing fatty matter. The growth appears in fact to be in some sense a kind of epithelioma. Molluscum has been supposed to be due to some abnormal development of the sebaceous glands; but both Beal and Virchow regard it rather as taking its origin in the hair-follicles. We believe, however, that we have seen molluscous tumours in the palm of the hand.

Whatever the nature of the disease may be, we consider that it has been clearly proved to be contagious. It frequently occurs simultaneously among the children of a family, and under such circumstances even the adult members occasionally become affected. The parts on which the tumours chiefly appear are the face, head and neck, and trunk; but they occur also on the limbs.

*Treatment.*—Local measures only are of use. If the tumours are attached by narrow bases they should be snipped off; if by broad bases, they should be effectually cauterised with nitrate of silver, potassa fusa, acid nitrate of mercury, or the like, previous to which it may be well to lay them open with a scalpel.

XX. LUPUS (*Noli me tangere*)

*Causation and description.*—The term ‘lupus’ is applied to a series of affections characterised by a specific overgrowth of the cutis, for the most part of chronic progress, and resulting in the formation of indelible cicatrices, or in more or less extensive destruction of tissue.

Lupus usually commences with congestion and hypertrophy of a limited area, which, in a large proportion of cases, is studded with solitary or grouped lenticular tubercles a line or two in diameter, and presenting a slightly translucent aspect and a dull red or pale salmon colour. The patch of congestion slowly increases in area or the tubercles in number, until in many cases a large extent of surface after a while becomes involved. While this extension is in progress various changes take place. In some

instances, the parts first implicated, without attaining any further stage of development, gradually lose their inflamed and hypertrophic character ; but, instead of simply reverting to the healthy condition, become pale, depressed and contracted, and assume a cicatricial character. In some instances, previously to the attainment of this cicatricial termination, their surface yields adherent scales or crusts. In some, the tubercles, almost from the beginning, are the seat of suppuration, and become crowned with thick adherent scabs. In some, extensive ulceration ensues, with grievous and irremediable destruction of parts. Lupus is generally regarded as a 'scrofulous' disease ; and it not unfrequently occurs in those who are suffering or have suffered from scrofulous suppuration of the cervical glands, or who are otherwise out of health ; moreover, exacerbations seem not unfrequently to be induced, in those who are already its subjects, by temporary conditions of general ill-health. Females suffer from lupus much more frequently than males, children than adults, and the poor than the well-to-do. The local symptoms which attend its progress are for the most part trivial ; often the patient makes no complaint, or, if he complains at all, complains only of itching or tingling. Structurally lupus appears to consist in the development of a kind of tissue, resembling granulation-tissue, composed of small cells with occasional giant-cells, imbedded, according to the density of the growth, in a greater or smaller quantity of fibrous material ; of tissue, indeed, closely resembling that of tubercle. Bacilli, apparently identical with those of true tubercle, have occasionally been discovered in the diseased tissues. There is good reason, therefore, to suspect that lupus is essentially cutaneous tuberculosis.

In accordance with the different peculiarities of character and progress which have been above referred to, several varieties of lupus have been described, the more important of which we shall now briefly discuss.

A. *Lupus erythematosus*, which was first described and named by Alibert, is the least severe form of the disease. It occurs mainly on the cheeks, nose, forehead, and scalp, but is not limited to these parts ; and it makes its appearance there in the form of rounded, erythematous patches, which slowly increase in diameter, and may at first be readily mistaken for patches of simple erythema. But sooner or later they get covered with either thin scales or thick crusts, composed largely of sebaceous matter, and continuous by their under surface with processes of the same material prolonged into the dilated orifices of the subjacent sebaceous glands. In the former case the affection simulates psoriasis ; in the latter, that morbid condition of the knuckles caused by dissection, to which Dr. Wilks has given the name of *verruca necrogenica*. The progress of lupus erythematosus is very chronic, and scarcely attended with any abnormal sensations, but when it subsides it leaves behind it permanent changes in the condition of the skin. It usually begins in adult life, and affects women more commonly than men.

B. *Lupus exedens* and *non-exedens* (*tubercular lupus*). -Lupus non-exedens, like the last, may occur on any part of the surface of the body,

but usually originates on the nose or cheek. It commences with the appearance of small tubercles, such as have been above described; which slowly increase in number, sometimes assuming an annular arrangement, and involve more and more of the contiguous cutaneous surface, extending, it may be, to the mucous membranes, and especially to that of the nose. Their course is very uncertain. Sometimes, after making but little progress, they slowly subside. More frequently they advance irregularly, now remaining quiescent for a while, now undergoing comparatively rapid extension, and thus, continuing for years, ultimately involve extensive tracts of skin. These become seamed and puckered, and of a greyish white colour in those parts which have undergone involution, and present groups of reddish tubercles in those which are still extending. In the progress of tubercular lupus, the tubercles not unfrequently become covered with scales or crusts, below which gradual erosion is going on, or undergo actual suppuration or ulceration with the formation of scabs. In some cases the tendency to suppurate or ulcerate, and to scab, forms a special feature in the disease, which then receives the name of *lupus exedens*. This leads to more or less rapid and extensive destruction of tissue, and when occurring (as it most frequently does) in connection with the nose, often involves the gradual loss of the septum nasi and cartilages which bound the nostrils. The cicatrization to which lupus non-exedens, and still more that to which the exedent form leads, is not merely in a high degree disfiguring, but often induces serious consequences. The eyelids become retracted, the nose curiously thin and pointed, the alæ contracted and the nostrils altered in shape, the mouth distorted, and the lower lip and chin drawn down upon the chest, as they sometimes are after extensive burns. The forms of lupus here described usually begin in early life, and are often prolonged by successive outbreaks to an advanced age.

*C. Pustular lupus.*—This variety of the disease simulates impetigo. It is sometimes limited to the face, and has then been termed by Mr. Startin ‘impetiginous lupus.’ Sometimes, however, the whole surface (head, face, trunk, limbs) becomes more or less thickly covered with it. The eruption consists of tubercles, which are mostly discrete, but are here and there collected into confluent patches, vary from  $\frac{1}{4}$  to  $\frac{1}{6}$  inch in diameter, tend to suppurate scantily at their most prominent points, and presently become crowned with small dark, hard scabs, deeply imbedded, and remaining fixed (unless detached by violence) for weeks or months. The detachment of one scab is liable to be followed by the formation of another; but sooner or later each tubercle gets absorbed, leaving behind it a temporary livid discoloration and a permanent depressed cicatrix. Pustular lupus is often associated with the presence of suppurating scrofulous glands.

*Treatment.*—In the treatment of lupus, constitutional remedies hold an important place. Among these the most efficacious are cod-liver oil, quinine, iron, and other forms of vegetable and mineral tonics, and arsenic. If there be a suspicion of syphilis (and it is often extremely difficult to

distinguish non-specific lupus from some forms of tubercular syphilide), the ordinary anti-syphilitic remedies must not be omitted. Change of air is often valuable. Local remedies are very variable in their effects; sometimes they seem to do more harm than good, sometimes their use appears to be followed by rapid amendment. In the tubercular form of the disease, especially if the tubercles be attended with ulceration or any other kind of destructive process, the use of solid nitrate of silver, potassa fusa, acid nitrate of mercury, or arsenical paste (made according to Mr. Startin's formula with three parts of arsenious acid, two parts of bisulphuret of mercury, and one part of calomel, together with water), is often highly advantageous. The caustic, however, needs to be repeated from time to time, and previous to its application the surface should be freed from scales and scabs. In the milder cases less severe local applications are usually indicated, such as nitric acid lotion, iodine paint, blistering fluids, or mercurial, lead, or zinc ointment. Removal of the diseased tissues by the knife is sometimes had recourse to. But more commonly the removal is effected by scraping by means of spoons specially devised for the purpose.

---

## XXI. RODENT ULCER

*Description.*—The affection known by this name occurs for the most part in persons above the age of 40, and usually appears in the upper part of the face, and more especially on the nose or eyelids. It begins as a pimple or wart, on which crusts form. The repeated removal of these leaves a small ulcer, which slowly enlarges and presents a smooth glazed surface, and an abrupt, somewhat thickened sinuous margin. The floor of the ulcer is indurated, as also are its margin and the surrounding skin. But there are no outlying tubercles, nor are the neighbouring glands enlarged. The ulcer yields scarcely any discharge, and is unattended with inflammation or pain. Its progress is remarkably slow, often extending over twenty or thirty years or more; sometimes it remains quiescent for long periods, sometimes it heals; but it is always liable to recur, and in its spread involves ruthlessly all neighbouring tissues, ultimately destroying it may be nose, eyes, jaw, causing deep excavations, and even exposing the surface of the brain. Rodent ulcer has a close structural resemblance to epithelioma, the cells and nests of cells, however, being very small compared with those of that disease.

*Treatment.*—The only effectual treatment is by the knife. But occasionally mercurial or other applications are beneficial, at any rate for a time.

---

## XXII. SARCOMA AND CARCINOMA.

A. With few if any exceptions the varieties of malignant disease originating in the skin are epithelioma and melanotic sarcoma : the former arising mainly where mucous membranes and skin meet, but often also in regions exposed to long-continued irritation; the latter springing up for the most part in pigmented *nævi* or warts.

B. The skin is often involved in the extension of malignant disease from subjacent parts. When sarcoma or cancer attacks the breast or bones or subcutaneous connective tissue, it usually sooner or later implicates the skin lying over it. The skin in such cases first becomes adherent to the growth below, and probably protruded by it; then it becomes infiltrated by it or incorporated in it; and soon convex or hemispherical nodules of various sizes, and irregularly distributed, spring from the surface. These tend to run together and to spread, and after a time to ulcerate or slough, and thus to terminate in characteristic areas of sloughy excavation, surrounded by fungating margins. Such extension, however, is not limited to malignant growths occurring in the limbs or organs superficially placed. Malignant disease of the œsophagus or trachea occasionally implicates the overlying skin. Mediastinal and other intrathoracic tumours not unfrequently involve the walls of the chest. Even peritoneal cancer at times makes its way to the surface, mainly at or in the neighbourhood of the umbilicus. And similar disease, whatever be its origin, developed in the venter of the ileum, tends to invade the integuments of the lower part of the abdomen or the upper part of the thigh, and to form outgrowths.

C. Among the most interesting cases, from the medical point of view, are those in which disseminated malignant tumours of the skin and subcutaneous connective tissue arise secondarily to similar disease originally developed in organs or tissues which have no direct connection with the parts thus secondarily affected. Such cases are rare; and hence, instead of venturing on a systematic description, we shall give brief details of two or three typical cases we have had the opportunity of observing. In one, a melanotic sarcoma affected secondarily the glands in the groin, and shortly afterwards large numbers of melanotic tumours appeared in the skin and subcutaneous connective tissue of the upper half of the front of the thigh, and lower part of the abdomen. The tumours were hemispherical and in some instances umbilicated, and varied when we saw them from the size of a pin's head to that of half a marble. The patient died of visceral melanosis. In another, a young woman had scirrhus of the breast, and of some of the abdominal organs. But, besides, she had numerous (probably two or three hundred) scirrhus tumours of the skin. Some of these existed on the face and in the extremities, but the great majority occupied the surface of the trunk. They were mostly hard plates, round, oval, or sinuous in outline, from an inch and a half in

diameter downwards, of variable thickness, slightly elevated, presenting a very definite margin, and occasionally a shallow central depression. Some were beneath the skin, which was movable over them; but most of them involved the skin in its whole thickness. Some of these presented a dusky or brownish hue, but otherwise their colour differed but little from that of the surrounding parts. The patient remained for two or three years under observation, finally dying of internal cancer. But during this period, while numbers of fresh cutaneous tumours made their appearance, several of the older ones underwent manifest atrophy. None (not even the cancerous breast) ulcerated. A third case was that of an elderly lady who showed, in her history and in the presence of growing abdominal tumours, clear indications of the gradual development of malignant disease. After her symptoms had continued for about six months, enlargement of some of the lymphatic glands above the clavicles and elsewhere was detected. Shortly afterwards, and about three months before her death, numerous small roundish hard growths appeared in the substance of the skin, and in the subcutaneous connective tissue. These were scattered irregularly over the arms, legs, and abdomen, but were as abundant on her face as the vesicles in confluent small-pox. They increased gradually in size until most of them were about as large as half a pea, and some as large as half a marble. At this time they tended to run together, and on the forehead and cheeks produced slightly irregular tracts of infiltration of considerable extent and thickness. The patient's aspect was not unlike that of leontiasis. The growths on the face were pale and greasy-looking; but many of those on the limbs and trunk were more or less deeply pigmented. A few pigmented excrescences appeared also on the fauces. The growths in the arms were mostly subcutaneous, and became so abundant that finally the arms felt almost like bags of peas. The disease was probably in this case, as in the first, sarcomatous.

D. Another variety of cutaneous sarcoma, which Alibert described under the name of *mycosis fungoides*, and of which a very remarkable example has been put on record by Dr. Payne,<sup>1</sup> is sufficiently characteristic to merit a brief description. The disease commences with the appearance of circular, oval, or band-like patches of various sizes and irregular distribution, which present a dusky red or brownish tint, and possibly a slight degree of elevation, most marked in the centre and diminishing towards the periphery. The area of discoloration involve head and neck, trunk and limbs, increase in size and tend to coalesce, and at the same time become thicker and here and there form distinctly tuberculated outgrowths. Up to this period the aspect of the patient, if the disease be extensive, is very suggestive of leprosy; and it is the more readily mistakable for leprosy because the parts affected present more or less anæsthesia, and slight febrile rises of temperature are apt to occur. The further progress of the malady, however, removes all doubt as to its nature. It continues to spread so that before long extensive tracts of skin,

<sup>1</sup> *Path. Trans.* vol. xxxvii.

possibly even its whole surface, become infiltrated with the growth, which forms in various regions, and perhaps more especially on the head and neck, large hemispherical or hemielliptical tumours, and thus causes enormous thickening and deformity. As the outgrowths increase, they become congested, tender and painful, excoriation and ulceration take place, and fungating granulations spring from the raw surfaces, which yield offensive and irritating discharges. The patient's distress during the later stages of his disease is very great. In cases to which the above description applies the course of the disease is rapid, and death ensues within a year or two, possibly even within a few months of its commencement. But cases, probably of the same kind, are met with in which the disease begins in some limited district with a few slowly-spreading nodular thickenings, and in which the progress of events extends over a considerable length of time, possibly many years. In Dr. Payne's case the growth involved the skin only, and on the head and neck measured from one to one and a half inches thick. It was sarcomatous and presented no micro-organisms. The internal organs were all healthy.

As to the *treatment* of the above affections there is little to be said. The first group belongs wholly to the surgeon. The second group demands no local treatment until ulceration and sloughing have occurred; and then only such applications as relieve pain and neutralise or prevent offensiveness of discharge. In the third group superficial destruction is uncommon, and there is for the most part absence of pain or even marked uneasiness. In the last variety of disease, local applications of a sedative and cleansing character are called for. And in this case, as also probably in the others, opium or other sedatives are sooner or later needed.

### XXIII. PHTHIRIASIS (*Lousiness*)

*Causation and description.*—Lice, the presence of which gives rise to the affection sometimes termed phthiriasis, are of common distribution as parasites throughout the animal kingdom. Three varieties affect man, namely, the *pediculus capitis*, the *pediculus vestimenti*, and the *phthirius* (or *pediculus*) *pubis*. The first of these as a rule inhabits the head only; the second lives in the underclothing, and feeds on those parts of the body which are uncovered with hair; the last infests the hair of the pubes and armpits, and less frequently the eyebrows, eyelashes, whiskers, beard, and moustache.

A. The *pediculus capitis* or *head-louse* is generally of a grey colour, like that of the scurf, and hence is very readily overlooked; it has, however, a dark streak (alimentary canal) along the central line of its body, the presence of which may aid in its detection. It lives among the hairs close to the scalp, feeding for the most part on the scurf and even on the hairs, and running along the latter with considerable agility. The female, which is larger than the male, deposits her eggs or *nits* upon the hairs,

attaching each one thereto by a tough transparent sheath. These, which may be readily mistaken for particles of scurf, are fixed upon the hairs much as are the cocoons of some moths upon the stalks of grass, are furnished with a lid, and measure about half a line in length. The female, according to Küchenmeister, begins to lay eggs at the end of eighteen days, and lays about fifty. They are hatched in six days.

Pediculi always cause more or less itching and consequently a tendency to scratch the head with the nails. This may be all. But in many cases the irritation which they produce leads to the development of eczema or impetigo, and the formation of thick scabs. As Mr. B. Squire has pointed out, impetigo in children limited to the back of the head is often of pedicular origin; and impetigo affecting the nape of the neck in adults (especially females) is also commonly attributable to lice. There is good reason to believe that the affection termed *plica Polonica* is nothing more than a combination of filth, lice, and entanglement or felting of the hair. Pediculi (then termed *p. tabescentium*) are very apt to accumulate in the heads of patients suffering from long and wasting illnesses. But there is no sufficient reason for regarding them as distinct from the common head-lice.

B. The *pediculus vestimenti* or *body-lice* is scarcely distinguishable from the last, excepting by its larger size, and its habits. It lives in the under-clothing, and attaches its eggs to the superficial projecting fibres. It is not always easy to detect its presence, for it is only occasionally discovered crawling upon the skin, or even upon the plane surface of the shirt or chemise. It almost always lies concealed in the folds or pleats; and it is in these situations also that its eggs are deposited. The eggs, moreover, though almost exactly resembling those of the head-lice, have generally so much the colour of the garment to which they adhere that they are seen with considerable difficulty.

Body-lice, like the last, often cause itching only; but often after a time the constant irritation of their presence leads to the development of an indistinctly papular condition of the skin, and bleeding points and lines, the consequence of violent scratching. This state of skin closely corresponds with the ordinary descriptions of *prurigo*. And indeed there can be no doubt that the great majority of cases of so-called *prurigo senilis* are essentially cases of phthiriasis. The presence of body-lice not unfrequently also causes urticaria, lichen, and eczema.

C. The *pediculus pubis* or *crab-lice* is very different in form from the other species of louse. It presents a much broader thorax and abdomen, and its chitinous claws are much more elongated and massive. It never affects any other parts than those which have already been named as its habitat; always nestling close to the skin, and biting deeply into it. It fixes its eggs, which resemble those of the head-lice, close to the points of emergence of the hairs.

The *pediculus pubis* causes violent irritation, and frequently induces an impetiginous eruption and the formation of abundant scabs.

*Treatment*.—It is usually not difficult to get rid of lice. The thorough

use of soap and water, and thorough personal cleanliness, are of course essential, but alone are not generally sufficient. Many local applications will destroy them, but none probably is more efficacious than daily washing with decoction of staphisagria seeds, or the inunction of the parts (as recommended by Mr. B. Squire) with oil of stavesacre diluted with olive-oil, or the application of mercurial ointment, such as the ammonio-chloride. The remedy must of course be continued until all nits (as well as lice) are removed or dead. It is often desirable, in order to promote certainty and rapidity of cure, to hunt out and destroy the pediculi one by one, to pluck or cut out the nit-bearing hairs, or even to shave the head or other hairy parts. The applications which have been enumerated are useful even in the treatment of the pediculus vestimenti, but the chief treatment here must be directed to the clothes. Not only, however, must these be frequently changed and washed, but the bed-clothes must be similarly treated, as also must the clothes of any one sharing the patient's bed.

#### XXIV. SCABIES (*Itch*)

*Causation and description.*—Itch is a skin-disease dependent on the presence of the *acarus scabiei*, and marked by the development of a papular, vesicular, or pustular eruption, with intolerable itching, which is especially violent in the evening and at night.

The *acarus scabiei* is not unlike a cheese-mite, both in general form and in colour, and is visible to the naked eye as a minute ovoid speck.

FIG. 38. FEMALE ACARUS SCABIEI  $\times 100$ . A. Ventral aspect. B. Dorsal aspect. C. Ova.

Its body has a short oval form, is convex above, somewhat flattened below, studded with numerous spines and bristles, and furnished (in the adult state) with eight legs. In the female the four front legs end in stalked suckers, the four hind legs in bristles. In the male the hinder-

most pair of legs, as well as the four front legs, present suckers. The acarus just escaped from the egg has six legs, the hindmost, or fourth pair, only making their appearance after the first change of skin. The male is little more than half the length and breadth of the female. The egg, which is oval, measures about one-third the length of the adult female.

The acari live for the most part in burrows (cuniculi) which they make for themselves in the substance of the epidermis, beneath its horny layer. According to Hebra, about a fortnight elapses from the time of hatching until the complete development of the animal. At the end of that time the impregnated female penetrates the corneous layer of the skin, and then slowly tunnels beneath it in a straight, zigzag, or curved line. In its onward progress it deposits eggs, sometimes as many as fifty, in a linear series; and at the end of two or three weeks, or it may be six (Hebra), it dies at the further end of its burrow. This may then have attained the length of half an inch, or an inch, or even more than that. It is generally quite obvious, on careful examination, as an irregular line studded with subcuticular black matter (*foeces*); presenting at its commencement, in consequence of the gradual desquamation of the skin, a groove with retreating sides (a kind of *calamus scriptorius*), and at its opposite extremity a minute papule, in which the white body of the animal can generally be pretty readily distinguished. The formation of the burrow and its full development may be unattended with any visible signs of inflammation; but not unfrequently papules, vesicles, or pustules rise up in its immediate neighbourhood, the burrow then passing over them, or alongside of them, but very rarely forming any communication with them. Sometimes strings of vesicles, running perhaps together, mark its whole length. The eggs contained within the burrow hatch there, and the young speedily migrate. The male acarus is difficult of detection, partly from its minuteness and comparative infrequency, and partly from the fact that it either simply imbeds itself in the skin without burrowing, or rambles over the general surface.

The acari mostly burrow about the wrists and the hands, especially on the palmar aspect, and between the fingers, and in the corresponding situations in the lower extremities; they also infest the nipples and organs of generation, the flexures of the elbows and knees, the axillæ and the buttocks. No part can be regarded as necessarily exempt from their ravages. The face and head, however, are rarely attacked. The presence of the acari causes intolerable itching, which increases at night-time, and provokes violent scratching. It also gives rise to inflammatory eruptions (papules, vesicles, blebs, or pustules), which are to be looked for especially on those parts of the surface which the acari chiefly affect; and occasionally it induces urticaria, eczema, or impetigo, which is not necessarily limited to the neighbourhood of the burrows, and may become general. The

FIG. 39. CUNICULI (natural size).  
The dotted circles indicate vesicles or pustules.

pustular variety shows itself for the most part in persons who are out of health or possess peculiarly susceptible skins. Sometimes the inflammation becomes excessive, and produces not only pustules but considerable inflammatory exudation and infiltration. This condition may often be observed in the penis and the nipples. The disease has naturally little or no tendency to spontaneous cure, but can certainly be kept in abeyance by personal cleanliness. Under opposite conditions, however, it is apt to become greatly aggravated. Occasionally the tips of the fingers and toes, with the nails, get destroyed, partly by the direct operation of the acari, partly by the ulceration which they induce. A very severe form of the disease, common in Norway (and hence termed *scabies Norvegica*), but not confined to that country, is characterised by the formation of thick tough crusts extending over the palmar surface of the hands and fingers, and the corresponding surface of the feet and toes, the parts beneath being excoriated or ulcerated. The crusts contain innumerable acari and ova, both living and dead.

From the different degrees of severity which it presents, and from the various eruptions to which it gives rise or with which it may be associated, itch is a disease which, on the one hand is apt to be overlooked when present, and, on the other hand, is liable to be assumed as present when the patient is entirely free from it. The appearance of a papular, vesicular or pustular itching eruption between the fingers and about the wrists, and in other situations which itch affects, is no doubt an important indication; but similar eruptions, not due to the acarus, occur in the same localities. The transference of the disease to a bedfellow, or to those with whom the patient has similarly close relations, is also a point of great significance; but it must not be forgotten that one member of a household may have itch for months and yet fail to infect any of the other members. The only real proof of its presence is the discovery of the acari, their eggs, or their burrows. The burrows are sometimes marvellously well seen, presenting all the characters which have been already described; but they are often incipient, and very difficult of recognition. When they are distinct the discovery of the female acarus is easy. It can generally be seen, even with the naked eye, at the further extremity of the burrow, or apparently a little beyond that point, as a very minute whitish papule. If the surface of this papule be torn with a pin, the acarus may readily be removed from its bed on the point of the instrument. In performing this operation it is well to avoid wounding any neighbouring vesicle or pustule. Even in cases where no obvious burrow exists, the acari may be occasionally detected in the neighbourhood of some of the itching papules by the presence there of the minute whitish elevations which they cause. Sometimes, even when distinct burrows are present, there is some difficulty in detecting the acari at their extremities; in such cases one of the burrows may be broken down, and its contents removed on the point of a pin or lancet, or still better, a whole burrow may be cut out. By these means the ova may be readily obtained. A further plan is to remove the scabs, if there be any, to boil them in a solution of caustic soda, until they

become limpid, and, after allowing the fluid to stand for a time in a conical glass, to examine the deposit with a microscope. Dead acari, including mites, and six-legged grubs, and eggs, can often be obtained by this process.

*Treatment.*—The essential object in the treatment of scabies is the destruction of the acari and their ova. For this purpose it is necessary, not only to apply an appropriate parasiticide, but to soften the skin and remove its superficial epidermis, so as to expose the burrowing mites to its influence. The patient therefore should have daily hot baths, use soap abundantly, and rub the surface thoroughly with a flesh-brush or a rough towel. All scabs should be removed. Then sulphur ointment, either of those of the Pharmacopœia, or that of Helmerich, which contains carbonate of potash, should be rubbed well into the skin, especially in those parts which seem most affected, and should remain upon the skin until the next bath. Treatment of this kind will generally cure itch in the course of a few days or a week, but may not improbably induce eczema or some other form of superficial inflammation, which will need other remedies for its cure. No doubt less active measures will suffice to cure scabies, but the cure will probably then be long delayed. On the whole, however, when a person has itch it is better for himself, in the long run, and better for those with whom he associates, that he should recognise his condition, retire for a few days from public life, and adopt the measures which will most speedily work a cure. Tincture of benzoin and balsam of Peru, far more agreeable applications than sulphur, are said to be more efficacious than it in the cure of itch. They should be rubbed well into the affected parts. The purification of the patient's clothes and bed-clothes forms an essential part of the treatment.

## XXV. OTHER SKIN-AFFECTIONS CAUSED BY ANIMALCULES

*Causation and description.*—*Fleas, bugs, and gnats* do not of course come under the category of parasitic animals. So many persons, however, suffer from their bites, and the effects of their bites are so often misinterpreted, that it seems desirable to make a remark or two in reference to them. A recent flea-bite always exhibits a punctiform subcutaneous extravasation of blood, surrounded by a comparatively broad rosy areola. The latter soon disappears; the former may persist for several days. People, and especially children, of the lower classes are often thickly covered with such petechial spots in different stages of their progress; and their skin, when seen for the first time (especially if they be suffering from some febrile disturbance), is very apt to suggest the presence of the typhus eruption. The smallness, however, of the spots, their uniformly petechial character, and the probable detection in them on close inspection of the puncture made by the insect, will alone, for the most part,

enable a careful observer to distinguish the eruption due to fleas from that of any of the specific fevers. In some persons flea-bites produce considerable irritation and the development of wheals or tubercles, sometimes associated with a large amount of subcutaneous effusion of serum. The effects are then not unlike those which commonly arise from the bites of gnats and bugs. In all these cases there is generally in the first instance violent itching, which is followed presently by the formation of a wheal or tubercle from the size of a split pea downwards, and often by more or less considerable subcutaneous œdema. The latter pretty soon subsides; but the wheal probably continues for a week or fortnight, and is generally attended with itching during the whole of that time. In its progress (owing in some measure to scratching) punctiform extravasations of blood often take place into its central part, and these are sometimes succeeded by vesication, or the formation of a pustule. Sometimes the wheals gradually subside and disappear; but in many cases their subsidence is attended with the separation of a squama, or the formation and detachment of an eschar, or, when there has been vesication or suppuration, the production of a scab. It need scarcely perhaps be said that gnats generally select exposed parts of the skin, fleas those regions which are protected by clothing, and that bugs are more indiscriminate in their attacks. There is no doubt that the bites of these insects, especially in children of delicate skin, produce eruptions the source and nature of which are often entirely overlooked. Many attacks of so-called 'strophulus,' 'lichen,' and 'impetigo,' ascribed to dentition, dyspepsia, and other causes, are really due to the operations of the above animals. *Mosquito*-bites are almost identical with gnat-bites in their effects; they are generally, however, much more numerous and individually more venomous.

The *leptus autumnalis*, or *harvest-bug*, which is common in the autumn in grass and cornfields and among gooseberry bushes, is very apt to imbed itself in the skin, and to cause much irritation there. The effects pass off in about a week. The mite, which is just visible to the naked eye, is of a red colour and presents six legs. It is probably the immature condition of an unrecognised eight-legged animal.

The *pulex penetrans* (*chigoe*) is a native of South America and the West Indies. It is so small as to be seen with difficulty, and is characterised by the possession of a proboscis as long as its body. Only the impregnated female attacks man. It penetrates the skin of the feet, and toes, generally in the neighbourhood of the nails, where its impregnated body quickly develops itself into a white vesicle the size of a pea. This enlargement is due to the rapid growth of the larvæ, which, if the cyst be ruptured, escape into the surrounding tissues and cause in them severe inflammation with suppuration. The recognised mode of treatment is to dilate with a needle the orifice by which the intruder entered, until it is large enough to allow of its extraction without rupture.

On the island of Bulama and its neighbourhood, on the West Coast of Africa, a pimple ultimately attaining the dimensions of a boil, and then attended with much pain and surrounding inflammation, and even affec-

tion of the neighbouring lymphatic glands, is attributable to the grub of some insect, which is deposited doubtless in the egg beneath the skin, and attains its full growth in that situation. The perfect insect is unknown.

The *acar* (*demodex*) *folliculorum* resides in the sebaceous follicles, for the most part in the duct or about the spot at which the sebaceous follicle opens into that of the hair. It is sluggish in its habits, and lies imbedded in the sebum with its head pointed inwards. The number of *acari* in a follicle varies from one upwards. As many as thirteen have been discovered at one time (Küchenmeister). They differ in size, and in some degree in form, with age. In the earlier period of their development they present six, and subsequently eight legs. They are most commonly found in the comedones of persons suffering from *acne punctata*, but do not cause this affection, or apparently aggravate it. In order to find them the expressed sebum should be diluted with oil, and then submitted to microscopic examination. This parasite causes no distinctive symptoms in man; but is said to produce serious and sometimes fatal consequences in the dog.

## XXVI. TINEA TONSURANS (*Porrig*o *scutulata*. Ringworm)

*Causation and description.*—Ringworm depends upon the presence of a fungus, termed *trichophyton tonsurans*, which chiefly affects the roots

A. Fine hair from trunk, showing mycelium and spores.

B. Hair from head, showing mycelium.

FIG. 49. TRICHOPHYTON TONSURANS  $\times 500$ .

and shafts of the hairs, but also invades the epidermis and nails. Its mycelium consists of filamentous jointed branching tubes, which in the

hair run in groups parallel with its long diameter, but in the epidermis and nails form an irregular interlacement. The spores are minute oval or rounded bodies, formed, in the first instance, in linear series at the extremities of the mycelial filaments; but soon so abundantly developed that this relation is entirely lost. Spores form both in the epidermis and in the nails, but their chief seat is the shafts of the hairs within and a little external to the skin. The fungus spreads superficially, as do most fungi, in gradually enlarging circles, which, however, from various accidental circumstances, are apt to expand irregularly, and often, when large, break up into irregular segments, and often, moreover, present fits of alternate quiescence and growth.

When ringworm occurs in the non-hairy skin, it reveals itself first as a slightly raised roundish uniformly erythematous patch, a line or two in diameter. This slowly increases in size, becoming at the same time more distinctly circular; and when it attains perhaps half an inch in diameter the inflammation at the centre begins to subside, and the patch thus becomes a ring. In its further progress the ring may enlarge to the size of half-a-crown, or a crown, and still extending (but then for the most part irregularly) may creep, for example, over the whole side of the face or front of the chest. The margin of the patch is always red and elevated, but varies in breadth, and often presents papules or vesicles; and hence the affection has been called indifferently *erythema circinatum*, *lichen circinatus*, and *herpes circinatus*. The central area, even if all inflammation appears to have subsided in it, still retains a yellowish or brownish discoloration, and a tendency to scale. Moreover, fresh spots of inflammation are apt to appear here and there upon it. Occasionally, patches of ringworm present two or three concentric erythematous rings, separated by rings of fairly healthy integument. This variety has often been termed *erythema*, *lichen*, or *herpes iris*.

When the nails are attacked, which is rare, they become in the affected parts irregular, thick, softer than natural, and at the same time more or less opaque and of a yellowish tint. The fungus penetrates them generally from the root and not unfrequently the adjoining surfaces of the fingers, and the hands, are at the same time involved.

The most important, if not the most common, seat of ringworm is the head. Here the circular form of the affection and its erythematous or vesicular margin are seldom distinguishable. The patches, however, are generally well circumscribed, and are indicated: partly by an abundant formation of adherent glistening scurf, which clings around the bases of the hairs, is continuous with the lining of the hair-sheaths, and, by its peculiar scaly character, has given to ringworm one of the names, *porrigo scutulata*, by which it was formerly known; and partly by the condition of the hairs, which become swollen, dull and opaque, limp and lacerable, so that they break off either at the surface of the scalp, or a line or two above it. This breaking off of the hairs produces a marked resemblance to a stubble-field, and has suggested the common name of the disease, *t. tonsurans*, or *tondens*. This stubbly character may be concealed, and

the surface rendered apparently bald, by accumulation of scurf. On removal of this many of the broken hairs are removed with it.

Ringworm sometimes in men attacks the beard, moustache, and whiskers, producing one of the varieties of *sycosis*. It there excites (as it does occasionally in the scalp) considerable inflammation, causing deep-seated suppuration about the sebaceous glands and roots of the hairs, and is very intractable.

Ringworm is generally attended with itching, especially if the head be the part affected. It is highly contagious, and is particularly liable to spread amongst children. Adults, however, especially those who are in attendance on affected children, often take it. But in them it is limited for the most part to the nails and fingers, and other non-hairy parts of the skin. Many suppose that it attacks mainly those who are in enfeebled health. But this is doubtful. When confined to the general surface it can, for the most part, be easily cured. In the head, beard, or nails, however, its eradication is extremely difficult and apt to be long delayed. Children may suffer from it for several years; and we have known it to persist in the finger-nails of an elderly lady for at least seven years, never during that time extending to other parts of her body. *Tinea tonsurans* affects the horse and some others of the lower animals.

*Treatment.*—The treatment of *tinea tonsurans* is purely local, the main object being to destroy or remove the fungus which produces it. Many substances are recommended as parasiticides, the most important being the sulphurous acid of the Pharmacopœia, mercurial ointments, and empyreumatic substances, such as *unguentum picis liquidum* (diluted or not), *unguentum creasoti*, oil of cade, and the like. In the treatment of ringworm of the head or beard, it is of great importance that the surface be kept close clipped or shaven, and, by washing with carbolic soap and water, free from scales or other kinds of exudation. Further, it is desirable that all affected hairs be removed from the morbid patches by daily diligent epilation. After each daily washing and epilation the specific medicament should be applied and kept applied: sulphurous acid by means of several folds of lint saturated with the solution and covered with oiled silk or paper; ointment by being rubbed in and then left in a thick coat on the surface. In the case of ringworm of the body, the same measures as to cleanliness and specific applications may be pursued; but here it is often advantageous to destroy the affected surface of the skin with some caustic, such as nitrate of silver, strong acetic acid, iodine paint, or blistering fluid. When the nails are involved, the surface should be removed in slices and sulphurous acid or creasote ointment freely and constantly applied.

Ringworm of the head and beard is very apt to reappear weeks or even months after apparent cure. The reason of this is of course obvious. It is important, therefore, that the treatment should be prolonged far beyond the period of apparent cure, and that the hairs of affected areas should be from time to time carefully examined. Dr. Duckworth has pointed out that if a few drops of chloroform be dropped on suspected portions of the

head, diseased hairs acquire an opaque yellowish-white colour, the healthy hairs remaining unaffected.

## XXVII. TINEA FAVOSA (*Favus. Porrigo avosa and Lupinosa*)

*Causation and description.*—The cause of favus is the growth in the skin of the fungus known as the *achorion Schönleinii*. This consists in a jointed mycelium, differing little from that of the trichophyton tonsurans, and like it invading the epidermis, nails, and hairs. It differs essentially, however, from the trichophyton in the seat and character of its fructification. The formation of sporules begins with the development of short rounded joints or sporules at the extremities of certain of the mycelial tubes, and a complex development of other sporules from them by budding. The first evidence of fructification to the naked eye consists in the appearance of minute disc-shaped sulphur yellow spots beneath the horny layer of the epidermis, or of minute yellow cups at the points of emergence of hairs. These gradually increase in size, until they form yellow cupped discs from  $\frac{1}{4}$  to  $\frac{1}{3}$  inch in diameter, through the centres of which hairs not unfrequently pass. On breaking these masses up they are found to be white within and brittle, and microscopically to consist of sporules seated in a finely granular matrix.

The early stage of favus, which is commonly overlooked, and is most obvious when the disease attacks the smoother parts of the body, consists,

A. Fine hair from trunk showing mycelium.

B. Mycelium and spores from neighbourhood of a favus cup.

FIG. 41. *ACHORION SCHÖNLEINII*  $\times 500$ .

like that of ringworm, in the appearance of small circles of erythema, which soon enlarge and become rings, and may then be studded with papules or vesicles. These rings of herpes or lichen circinatus rarely

grow larger than a sixpence or a shilling and are at first absolutely undistinguishable from those of ringworm ; but soon there appear here and there at the edges or over the surface of the discs the characteristic yellow points of fructification ; and these rapidly attain their full dimensions. The mature favi, if discrete, maintain their characteristic form and appearance ; but where many of them are developed in close contiguity with one another they are apt to blend, and before long to form a prominent, irregular, mortary mass crossed superficially by an imperfect network of undermined epidermis, and presenting collectively an appearance not altogether unlike that of a rupial scab. Not unfrequently the progress of favus is attended with considerable inflammation, and even suppuration, the products of which blend with those of the vegetable growth. Under these circumstances the neighbouring lymphatic glands also become inflamed. As a rule, however, favus is attended with little local irritation, and little itching. It is characterised generally by a peculiar mousy odour.

Favus most frequently attacks the head, and leads to the falling out of the hair, and the growth in its place of thin, colourless, woolly hairs, and often causes eventually total destruction of the hair-follicles, and permanent baldness. The affected hairs, however, are not rendered brittle as in *tinea tonsurans*, and therefore do not break off. Nails attacked with favus do not differ appreciably from those which are the seat of ringworm.

Favus is rare in England, but in Scotland appears to be somewhat common. It is limited almost entirely to persons of filthy habits, and generally begins in childhood. When treated in its early stage it is easily cured ; but when it has infected a large area it is exceedingly intractable, and will often (notwithstanding careful treatment) persist for many years. That this, like other parasitic diseases, is infectious, is beyond doubt ; nevertheless, it is remarkable how rarely (compared with *tinea tonsurans*) it spreads among children, or from one member of a family to another. Favus is a common and fatal disease in mice. Cats also sometimes suffer from it.

*Treatment.*—The principles and details of the treatment of favus are as nearly as possible identical with those of the treatment of ringworm. In the first place all the favi should be removed by washing, poulticing, or the employment of oleaginous applications. Then the surface should be kept scrupulously clean, and treated with such parasiticide remedies as are useful in ringworm. Persistent epilation is of essential importance. In severe cases it is necessary to continue the treatment for many months, a year, or longer. Yet even when thus apparently cured, it not unfrequently breaks out again as soon as treatment is discontinued.

---

XXVIII. TINEA VERSICOLOR (*Pityriasis Versicolor*. *Chloasma*)

*Causation and description.*—This disease is caused by the growth among the epidermic cells of a fungus, termed the *microsporon furfur*. The mycelial tubes are about equal in thickness to those of the fungi which have been above described, but their texture is more delicate. They form an interlacement in the substance of the epidermis, but do not invade the hairs or nails. The spores are developed in microscopic clusters, somewhat resembling bunches of grapes, scattered here and there among the mycelial tubes, and seem to originate within buds springing from the sides or ends of certain of the cells of the mycelium.

Chloasma is characterised by the formation of light-brown or liver-coloured spots which are slightly elevated above the general surface of the skin, covered with a more or less abundant branny scurf, and attended with slight itching. The primary spots have a circular outline, and vary

A. Epidermis showing spores and mycelium  $\times 250$ .

FIG. 42. MICROSPORON FURFUR.

perhaps from the third or fourth of an inch in diameter downwards. In the first instance a few such spots appear here and there. These increase in size, and soon other similar spots arise in their vicinity. By degrees neighbouring spots blend, and thus more or less extensive tracts of skin become pretty uniformly covered, the edges still presenting a sinuous character, and the neighbourhood numerous outlying solitary and coalescing islets.

Chloasma seems never to attack children, and very seldom persons of cleanly habits and among the better classes of society. It is a disease of adult life, and not unfrequently appears in those who are consumptive

or otherwise out of health. It usually commences on the chest or between the shoulders; and thence may spread, over the abdomen and back, to the shoulders, upper arms and even forearms, and to the buttocks and thighs. But it never affects uncovered parts. This circumstance, together with the fact of its occurring mainly in those who wash little and

seldom change their linen, seems to indicate that the disease originates in filth. Like other parasitic diseases it is contagious, but its contagiousness is not well marked.

*Treatment.*—In the treatment of chloasma perfect cleanliness is necessary. The affected parts should be daily washed with soap and water and well scrubbed with a flesh-brush or rough towel; after which one of the parasiticide applications should be well rubbed in. Under these measures the disease soon becomes apparently cured. Its complete cure, however, demands persistence in treatment long after all visible traces of the disease have disappeared.

---

## XXIX. ERYTHRASMA (*Eczema marginatum parasitarium*)

*Causation and description.*—An affection having a considerable resemblance to chloasma, but apparently arising only in parts which are kept moist, and especially in such as where, from the constant contact of opposed surfaces, the skin is sodden with perspiration. The usual seats are the upper part of the thigh against which the scrotum rests, and the axilla. It is said to begin in the form of circular patches, which gradually extend, until, for example on the thigh, the patch occupies almost the exact area of contact with the scrotum. The morbid surface has a brownish or dead-leaf colour, and is inclined to be scaly. The margin is abrupt, somewhat thickened, and a little more congested than the rest of the surface. The affection is sometimes attended with itching, but is often free from discomfort. Its contagiousness is very slight, and it often remains limited to the region primarily affected. It is said to be very intractable. In unprepared microscopic specimens of the affected epidermis it is very difficult to detect anything abnormal; but by staining with methyl-violet an organism, much more minute than those found in other skin-diseases known to be due to vegetable parasites, and presenting mycelial threads and cocci, becomes abundantly visible in the epidermic scales. Von Bärensprung, who first described it, gives it the name of *microsporon minutissimum*.

The same *treatment* may be employed for this affection as for chloasma.

---

## XXX. ALOPECIA AREATA

(*A. circumscripta. Porrigo or Tinea Decalvans*)

*Causation and description.*—This is an affection mainly of the hairy scalp, but occasionally also involves the eyebrows and eyelashes, the beard and whiskers, the hair of the armpits and pubes, and, it may be, even the general surface of the skin, and is characterised by the tempo-

rary or permanent loss of hair in more or less distinctly circumscribed area.

A well-developed patch of alopecia areata of the scalp is usually unmistakable. It is a well-defined bald surface of circular or sinuous outline for the most part clean, smooth, and shining, and free from congestion or scurfiness. The skin indeed appears to be, if anything, thinner than in health, and the orifices whence the hairs should emerge are atrophied and indistinct. The patch may be perfectly bald in its whole extent, or may present here and there groups of such downy hairs as constitute the lanugo; but not unfrequently a few long hairs still stud its surface at distant

FIG. 43. A. Diagrammatic profile view of edge of patch of alopecia. Natural size. (a) Healthy hairs; (b) shrunken and broken hairs. B. Shrunken and broken hair  $\times 10$ .

intervals; and often in the neighbourhood of these and of the margin may be seen on close inspection short club-shaped hairs, varying from about a line to  $\frac{1}{4}$  or  $\frac{1}{2}$  inch in length. These are most obvious in dark-haired persons, from the fact that each clubbed free extremity still presents the natural dark colour; but the portion of the shaft between it and the scalp becomes more and more attenuated and more and more devoid of colour as it approaches the latter. They can be pulled out more readily than healthy hairs, but still are generally attached with some degree of firmness. Their presence may be taken as indicative of the extension of the disease. When the alopecia has become arrested, downy hairs begin to show themselves over the bald area; and these may gradually assume all the characters of the surrounding healthy hairs, or become coarse, and white or otherwise modified in colour, or may remain weak and scanty. Sometimes new hairs grow up in the centre, while the disease is still spreading circumferentially.

Alopecia areata is for the most part of chronic progress, lasting generally for months, often for years, or even for life. In some cases the patient presents only one or two circular spots, which enlarge up to a certain point and then undergo resolution. In some cases the disease continues to extend indefinitely, partly by the enlargement of old patches, partly by the development of new ones, until the greater part of the scalp or even the whole scalp is involved, and until, maybe, the eyelashes and eyebrows, one after the other, and finally all other collections of hair disappear. Occasionally the progress of the disease is acute, the hair falling out rapidly and generally, though still perhaps more or less patchily. The final issue of the disease is uncertain. In the great majority of cases recovery takes place after a longer or shorter time; but there is still a tendency for the disease to recur at irregular intervals, and not necessarily in the part originally affected. In no inconsiderable number of cases, and especially in those in which extensive tracts of

surface have suffered, complete restoration of the hair never occurs. And, in a few, absolute and permanent general alopecia ensues.

The clubbed hairs above referred to present certain peculiarities of microscopic structure. The clubbed end is usually broken into a brush, and frequently presents in its interior an irregular group of largish cells, which are evidently the cells of the axis of the hair, at that part, modified in character. From this point downwards the hair becomes more and more attenuated, until it ends in a very slightly dilated point, which represents the imperfect root. Occasionally, a little below the clubbed extremity, the dwindling shaft is interrupted by a small knot, within which such a group of cells exists as is usually found in the clubbed end itself. Looking to the fact of the occurrence in the originally healthy hair, at a point which seems to separate the normal from the attenuated portion, of a spot in which there has been some sudden modification of nutrition and growth which renders the hair at this part brittle and peculiar in structure; and to the fact that the portion of the shaft subsequently formed becomes, in consequence of the gradual wasting of the hair-root, more and more attenuated, until it falls out bodily; it would seem pretty certain that the diseased process, as it affects the hairs, depends on the gradual spreading from some central point or points of a wave of inflammatory or other influence which, as it passes over each hair-papilla, momentarily excites it as it were to unhealthy over-production, and then leaves it enfeebled and perishing. This disease is asserted by Bazin and many others to be parasitic, and due to the presence of the *microsporon Audouini*. There can be little doubt, however, that this view is erroneous. It is believed also by many to be contagious; but this, again, is doubtless an error. It is certain, however, that it is apt, like psoriasis, to break out periodically in the same individual, and like that also to affect several members of the same family, and to be transmissible from parent to child. The disease is more common in children than adults, and in females than males. We have seen it in a child ten months old, and it is often met with, still progressing, in persons between forty and fifty. Its presence is neither preceded nor accompanied by any general signs of ill-health; nor is its progress usually attended with any subjective local symptoms. Occasionally its commencement and spread are marked by tingling or itching, so that the experienced patient not only knows, before the hair falls out, when a new patch of disease is commencing, but knows also when an old patch is spreading.

*Treatment.*—The treatment of alopecia areata is very unsatisfactory. Many patients get well who are never subjected to any, and many go on progressively from bad to worse in spite of the most sedulous care. There are no obvious indications for constitutional treatment, but tonics and arsenic are often employed empirically. For local medication it is generally thought best to use stimulants, and especially to blister the affected regions periodically with the *acetum cantharidis* or iodine paint. We do not believe that shaving the head is of any use, excepting for the purpose of facilitating the application of local remedies. Those who believe in the

parasitic nature of the disease would naturally use creasote, sulphurous acid, or other parasitocides.

---

### XXXI. ATROPHY

The skin and organs connected with it, like all other parts of the body, are liable to undergo atrophic changes. Not the least important of these are the whitening of hair, and baldness, and the dryness, thinness, and scaliness of skin, which are among the characteristic evidences of advancing years. In many diseases, especially such as are of long duration and attended with progressive emaciation and debility, atrophic phenomena of a like or closely allied nature often make their appearance. To all these we merely allude. There are two forms of atrophy, however, which may conveniently be briefly considered in this place.

A. *Glossy skin* is the name which was applied by Paget to an atrophic condition of the skin of the fingers coming on after injury to the nerves supplying them. In this affection, in addition to a constant burning pain which is generally present, the fingers become notably attenuated and tapering, the skin thin, smooth, shining, and of a uniform rosy tint or mottled with red blotches, as if from the presence of permanent chilblains; the nails get thin and curved, and long from retraction of the skin covering their roots; and the hair and other appendages dwindle or disappear. Moreover, there is a tendency for the affected parts to become relatively cold, and for the joints to enlarge, stiffen, and even become ankylosed. The affection here described may involve the hand as well as the fingers, and has been met with in the toes and feet. It may be due to disease or injury of the cord, as well as to disease or injury of nerves.

B. *Linear atrophy* is the name sometimes given to the 'lineæ albicantes,' or white lines, which commonly appear in the abdominal walls and upper parts of the thighs of pregnant women, and in the breasts of those who are suckling. Such atrophic lines are also frequently met with in persons who are suffering from ascites or ovarian tumour, or, in fact, any affection causing abdominal distension, and are occasionally observed in limbs which have been anasarcaous. In all these cases they are obviously due to stretching and interstitial giving way of the skin. They always appear in the parts where the stretching has been greatest, and their direction tends to be at right angles to that in which the force producing them chiefly acts.

Now and then similar atrophic lines appear in groups in patients who are suffering from acute febrile or inflammatory disorders, such as enteric fever and intrathoracic inflammation; in persons labouring under chronic wasting diseases; and even in such as are apparently healthy. They then arise quite independently of any obvious stretching of the skin; and in some instances, at any rate, seem to be determined by pressure. Under

such circumstances, a common seat is the lower part of one or other side of the chest behind, the loin, the buttock, or the thigh.

The atrophic lines are usually irregularly lanceolate in form, various in length and breadth, whiter and softer than the surrounding skin, slightly depressed, finely wrinkled, and presenting a scar-like aspect. Occasionally, when for example they are developed without obvious cause on a part of one of the limbs, they are few in number, several inches long, and of proportionate breadth. More frequently, as when they appear in pregnancy, they are smaller, very abundant, and arranged more or less in parallel groups, but tending to run into one another. And not uncommonly their arrangement reminds one of that of the ripples of sand left by the retreating tide ; or they form an irregular network.

In their commencement the atrophic lines are indicated by rosy redness and delicate desquamation of cuticle, appearances suggestive of the presence of very slight superficial cutaneous inflammation, with tendency to excoriation. At this time, too, there is often considerable itching of the affected parts. The cicatricial character is acquired later.

No *treatment* is called for in linear atrophy. The treatment of glossy skin is mainly that of the nervous disorder on which it depends. Under the continued use of the constant current sometimes a cure, and often great improvement, take place.

---

## XXXII. PRURIGO

*Description.*—This name is given to a condition of the skin, attended with more or less violent itching, and usually marked by coarseness of texture, and the presence of scratches produced by the action of the finger-nails. It is uncertain whether there is any specific affection to which the name is applicable. Willan obviously included under this term mere pruritus, or itching from various causes, and especially that due to the presence of body-lice. But he also included a papular affection, which he regarded as quite distinct from other varieties of papular diseases. Hebra also describes a similar affection, which he considers to be *sui generis*, and to which he limits the use of the name.

According to the latter authority prurigo is a disease of remarkable intractableness, if not incurable, consisting in the development of flat papules, not differing in colour from the skin, scarcely appreciable by the eye, but readily detectable by the touch, and leading to a general coarseness of texture and more or less pigmental deposit. It may occur upon nearly all parts of the body, though rarely attacking all in the same individual ; and it especially affects in an increasing ratio the front and back of the trunk, and the extensor aspects of the upper arms and thighs, fore-arms and legs. The papules are apt to be irritated into inflammation or torn by scratching, and the eruption to be complicated, after a time, with eczema, impetigo, urticaria, and the like. Notwithstanding Hebra's

authority, it may still, we think, be a question whether prurigo does not represent a heterogeneous group of ill-developed or ill-defined affections, attended with the common symptoms of intense itching, and in which a coarse sub-papular condition of skin is present, in consequence partly of some abnormal nutritive condition of the skin, partly of the influence of constant scratching and other varieties of irritation. According to this view, prurigo may be a legacy left by eczema, impetigo, or erythema; or it may be present in persons liable to these affections during the periods when they seem to be free from them; or it may be referrible to phthiriasis or scabies, to jaundice or uræmia, to want of cleanliness, to the irritation produced in delicate skins by the too abundant and too frequent use of soap, or to excessive friction either by the towel or by the clothes.

*Treatment.*—For the treatment of prurigo Hebra especially recommends sulphur, in the form of ointment, baths, or fumigation, tar in its various preparations, creasote, and frequent bathing. Besides these remedies lotions may be employed containing opium, prussic acid, acetate of lead, acetate of ammonia, or vinegar, or else black-wash, or mercurial or plumbic ointments. The constitutional treatment must depend on the patient's general symptoms or state of health, or on the nature of the ailment to which the pruritus is referrible. When the itching is due to parasitic affections, prarasiticide applications must be employed.

---

### XXXIII. CONCLUDING REMARKS

Besides the various affections of the skin which have just been passed in review, there are many others, of more or less interest, which could not be omitted from a work devoted to skin diseases, yet scarcely call for consideration in a manual of medicine. They are either of no practical importance, or they are extremely rare, or they fall entirely within the domain of the surgeon, or they are mere symptoms of more important disorders, and considered, so far as is necessary, elsewhere in this volume. We allude more particularly to such hypertrophic affections as horns, corns, warts, nævi, fibromatous and fatty tumours, epithelioma and other varieties of malignant disease which affect the skin primarily; to various atrophic conditions of the skin, hair, and nails; to increase or diminution of pigment (*ephelis*, *lentigo*, *vitaligo*, *albinism*); to the eruptions characteristic of many specific febrile disorders, and those caused by certain articles of diet or certain drugs; and to such rare or ill-understood affections as *frambæsia*, *pellagra*, and *acrodynia*.

## CHAP. III.—DISEASES OF THE RESPIRATORY ORGANS

### I. INTRODUCTORY REMARKS

#### A. Anatomical Relations

1. The *organs of respiration* comprise the larynx, trachea, bronchial tubes, lungs, and pleuræ.

*Larynx and trachea.*—The larynx is situated in the upper and fore part of the neck, extending from the hyoid bone above to the lower border of the cricoid cartilage below. The trachea commences at the lower border of the larynx, on a level with the upper orifice of the œsophagus and the fifth cervical vertebra, and runs downwards in the mesial line to the level of the third or fourth dorsal vertebra, where it divides into the two bronchi. The upper half of it is situated in the neck, the lower half in the chest behind the sternum. Behind, it lies in con-

FIG. 44. Diagram showing relations of lungs, trachea, and bronchi to the osseous framework and surface of chest. Front view. *a* and *b*, 1st and 12th dorsal vertebrae.

tact in its whole length with the œsophagus. In front, it is embraced above, as low down as the fourth, fifth, or sixth ring, by the thyroid body, and below, just above its bifurcation, is crossed by the transverse arch of the aorta. The roots of the lungs are situated in the posterior mediastinum, on the level of the bodies of the fourth and fifth dorsal vertebrae; the right bronchus, which is nearly horizontal, being on the level of the fourth vertebra behind and second costal cartilage in front; the left, which passes down obliquely, reaching as low down as the fifth vertebra behind, and a little below the second costal cartilage in front. The latter passes under the aortic arch, and is therefore in contact, above with the transverse arch, behind with its descending portion.

*Lungs.*—The apex of each lung rises above the first rib into the root of the neck, and the posterior obtuse margin occupies the groove between the ribs and vertebræ as low down as the eleventh rib. The base of the lung varies in position with the varying position of the diaphragm. The vault of the diaphragm rises during expiration on the right side to the level of the fifth rib at the sternum, on the left to the level of the sixth, and

FIG. 45. Similar diagram to last. Back view.

of course therefore the liver on the right side and the stomach on the left attain these respective elevations. The outer margin of the base, however, owing to the upward convexity of the diaphragm, reaches to a lower level, and during medium distension of the lungs with air may be traced in nearly a direct line from the junction of the sixth costal cartilage with

the sternum outwards and downwards to the head of the eleventh rib. During deep inspiration the edge may descend considerably between these extreme points. The anterior margin, like the lower one, varies in its position during the respiratory acts. When the lungs are moderately full their anterior borders are separated above by a triangular interval, the base of which corresponds to the sternal notch, the apex to the lower edge of the manubrium. From this point downwards to the interval between the fourth ribs, they continue parallel and nearly in contact. They then separate again, the edge of the right lung still passing vertically downwards, while that of the left retreats, forming a notch of which the apex corresponds to the junction of the fifth costal cartilage and rib, or to a corresponding point in the fifth interspace, and within which the heart becomes superficial. After a deep inspiration the anterior edges of the lungs are usually in contact from above down to the commencement of the cardiac notch; after a deep expiration there may be an interval of an inch or two between them. The extreme apex of the lower lobe of either side is situated behind, and in the adult about three inches below the summit of the lung.

*Pleura.*—The cavities contained by the parietal pleuræ correspond pretty accurately to the forms of the lungs; they are, however, only fully occupied by the lungs when these are largely inflated. During ordinary respiration there is a portion of each pleural cavity beyond the lower

margin of the lung, and another beyond the anterior margin, in which opposed portions of the parietal pleura are in contact with one another. The pleuræ do not line the thoracic parietes quite down to the attachment of the diaphragm in front; and, further, while the anterior margin of the right pleura extends to the mesial line of the sternum from the level of the second rib downwards, that of the left retreats somewhat at about the point at which the notch in the left lung commences.

2. *Regions of chest*.—It is usual and convenient for clinical purposes to map out the chest into regions. The names of those which are generally recognised sufficiently indicate their respective positions. They are as follows:—in front, the *supra-sternal*, situated immediately above the sternal notch; the *upper sternal*, corresponding to the upper half, the *lower sternal* to the lower half, of the sternum; the *supra-clavicular*, placed just above the inner half of the clavicle; the *clavicular*, corresponding to the inner half of the same bone; the *infra-clavicular*, extending from the clavicle downwards to about the level of the third rib; the *mammary*, of which the nipple may be taken as the centre, extending from about the third to the sixth rib; and the *infra-mammary*, comprising the remainder of the front of the chest;—at the side, the *axillary*, bounded by the summit of the axilla above, in front and behind by the axillary folds, and extending half-way down the thorax, and the *infra-axillary*, occupying the lower half of the lateral aspect of the chest;—at the back, the *upper scapular*, situated above the spine of the scapula; the *lower scapular*, corresponding to the infraspinous fossa; the *inter-scapular*, lying between the vertebral border of the scapula and the spinous processes of the vertebræ; and, lastly, the *infra-scapular*, including all that part of the back of the chest situated below the lower angle of the scapula. We have not assigned exact limits to all of these regions, partly because different writers assign different limits to them, partly because, convenient though they are for ordinary purposes, it seems to us preferable, when there is need of exactitude, to define the position and limits of areas by reference to the ribs and other fixed landmarks, and by measurement.

### B. *Pathology of Voice, Respiration, Cough, and Expectoration.*

In the investigation of diseases, and more especially those of the respiratory organs, much information may often be obtained by attention to any peculiarities which the voice or respiratory acts may evince, to the presence or absence of cough and to the quality of the cough, and to the character of the expectoration.

1. *Voice*.—The voice may be feeble, tremulous, or absent, its quality or its pitch may be changed, and its register or compass may be contracted or modified.

Mere *feebleness of voice* is so commonly associated with the presence of diseases, whether in the lungs or elsewhere, which cause enfeeblement of the muscular system generally, that it attracts comparatively little notice. It depends essentially on feebleness or imperfection of the

expiratory act, however these conditions may be brought about. Hence we meet with it whenever there is much dyspnoea present, especially if at the same time the respirations be hurried and shallow; and it is a notable characteristic of all cases in which, whether from disease of the spinal cord high up, or from any other cause, the diaphragm or the intercostal muscles or the muscles of expiration are paralysed or weakened. Tremulous or bleating voice arises from want of accurate control over the expiratory muscles or over those of the larynx itself. It is met with chiefly in old age and in persons who are hysterical or nervous.

*Absence of voice*, that is to say, total inability to produce laryngeal intonation, and the capability of evolving only that wheezy sound which forms the basis of all whispered vowels, indicates either that there is some functional inco-ordination of the organs concerned in phonation, or that the patient is unable to bring the vocal cords into apposition, and that the rima glottidis remains during his attempts at phonation in that patent condition which it affects during ordinary respiration, or that possibly there is paralysis of the arytenoideus alone. The first condition is probably always hysterical; the second is largely hysterical, but may also be caused by organic disease; the last is usually the result of some catarrhal affection.

The *pitch of the voice* depends on the action of the larynx alone. There are two widely different diseases in which the voice very frequently becomes markedly high-pitched or squeaky; these are Asiatic cholera and leprosy. It becomes high-pitched also in those who are under the influence of laughing gas. Trousseau points out that when there is lesion of the superior laryngeal nerves alone, there is, owing to the consequent paralysis of the crico-thyroid muscles, inability to utter the higher notes, and the voice consequently becomes deep-toned; and further that in some cases of laryngeal inflammation, attended with hoarseness, the voice is low-toned on first rising, and becomes higher as the day advances. It is obvious that in the last two cases the *compass of the voice* also must be contracted.

Pathological changes in the *quality of the voice* are largely dependent on conditions external to the larynx. It is thus that it gets altered when the faucial passage is narrowed by the presence of enlarged tonsils, when the soft palate is stiff and sore from inflammation, or paralysed after diphtheria, or when there is cleft palate. Hoarseness or roughness of voice (in other words, loss or impairment of the musical quality of the voice) may depend upon any circumstance which interferes with the regular vibration of one or both of the vocal cords. Thus it may arise from inflammatory or other thickening of the cords, from ulceration, from the presence of warty or other growths, or from the adhesion of mucus or other matters to their surface; and it is not unfrequently due simply to the fact that while one cord acts perfectly, the other cord is paralysed. Hoarseness passes on the one hand into the normal intonation of the voice, on the other into absolute aphonia.

2. *Respiration*.—Ordinary quiet breathing is effected without appreciable effort, and with scarcely audible sound, at the rate, in the adult, of

from sixteen to twenty respirations in the minute : their number having to the beats of the pulse a ratio of about one to four or five, and the act of inspiration being probably somewhat longer than that of expiration. The respiratory acts are liable in health, and still more in disease, to many deviations from the above rules : they may be modified in frequency, depth, and strength, and may be attended with more or less noise, discomfort, and effort.

*The frequency of respiration* is diminished in syncope and collapse and various affections implicating the nervous centres, and occasionally also in cases of dyspnœa dependent on the presence of some mechanical obstacle to the entrance and escape of air. It is generally increased in inflammatory and febrile disorders, in affections of the lungs, pleuræ and heart, and above all, in some forms of hysteria, in which indeed the acts have been known to exceed one hundred in the minute. The *depth* of the respiratory acts is usually in inverse proportion to their frequency. Hence when they are rapid, they are also, as a rule, shallow and inefficient ; when abnormally slow they are deep and laboured. Under these latter circumstances especially, the relative duration of inspiration and expiration is frequently considerably altered ; in some cases, as in certain forms of gastro-intestinal disturbance and in some varieties of cardiac affections, the inspirations are prolonged and sighing ; in others, and more especially in cases of emphysema, asthma, and mechanical obstruction of the larynx or trachea, the duration of expiration becomes relatively largely increased. The respiratory rhythm is affected in another way in a variety of breathing to which Dr. Stokes has called special attention, which only occurs in a marked form when death is impending, chiefly, he thinks, in cases of enfeebled heart, but also in brain-diseases. It consists of alternate periods, lasting for a few seconds each, of hurried breathing, and complete arrest of respiratory efforts ; the respirations of each respiratory period beginning feebly and at comparatively distant intervals, increasing rapidly to a maximum in frequency and depth, and then gradually dying away. The term ‘Cheyne-Stokes’ breathing is often applied to this phenomenon.

The term *dyspnœa* is employed of all cases in which respiration is unusually rapid, and equally of all those in which it is unusually slow, or even of normal rate, but attended with marked exertion. The special muscular efforts which accompany and indicate dyspnœa are apparently limited in some cases to the dilatation of the nares during each inspiration, in some to this act in conjunction with rhythmical opening of the mouth ; in other cases the muscles of the neck also act more or less powerfully ; and between these conditions and the phenomena of the asthmatic paroxysm, in which breathing is effected with agonising efforts, and every ordinary and extraordinary muscle of respiration is called into powerful action, there are all gradations. The abnormal sounds which attend dyspnœa are sometimes a sniffing sound produced in the nares, sometimes a sucking or sipping sound manufactured with the lips, sometimes a panting sound effected in the throat.

Further, whenever the rima glottidis is narrowed, and incapable of

enlarging to permit the free passage of the breath, or the trachea is diminished in calibre, as it may be from the presence of a diphtheritic membrane, or the pressure of an aneurysmal tumour, both inspiration and expiration acquire what is called a 'stridulous' character; they become remarkably harsh and rough, presenting in some cases almost a metallic ring. These peculiarities are always greatly increased when respiration is hurried, or during the inspiration which precedes a cough. Closely related acoustically to stridor is wheezing or whistling, which is a common attendant on old bronchitis, and always accompanies the asthmatic paroxysm.

3. *Cough* is a modification of breathing characterised by the occurrence of one or more short but violent or spasmodic expiratory acts, in association with more or less complete closure of the glottis, and usually preceded or followed by a deep inspiration. It is generally excited by some irritation or abnormal accumulation, at the glottis, in the trachea, or in the larger bronchial tubes; or it is a simple nervous affection. The act of coughing is generally preceded by tickling or some other uncomfortable sensation referrible either to the larynx or to some part of the trachea. The cough may be unattended with expectoration or dry, either because there is nothing to be expectorated, or because the offending matter cannot be dislodged; or it may be accompanied by more or less abundant discharge of mucus or other matters. In the first case the cough may be that of the early or dry stage of inflammation, or of whooping-cough, or it may be a nervous disorder. In the second case (that in which the cough is ineffectual) there is probably some mechanical obstacle in the larynx or trachea to the discharge of peccant matter, or clogging of the bronchial tubes with tenacious or even solid material, or limitation of the mucus to some of the smaller tubes. The third case does not call for special remark.

All coughs are from their very nature *spasmodic*; but some, from the entire want of control which patients have over them, and from peculiarities which they present, are especially deserving of that epithet. The most remarkable of these are the paroxysmal coughs which characterise pertussis, obstruction of the trachea, and spasmodic croup. In pertussis there is a rapid succession of spasmodic expiratory efforts, continued until further expiration is mechanically impossible, and then a long inspiration, effected through the spasmodically closed glottis, and yielding the characteristic whoop. In spasmodic croup a series of coughs also occurs, the expirations being remarkably harsh and noisy, the inspirations attended with a whistling sound. In tracheal obstruction, the inspirations are prolonged, stridulous, and wheezing, the expirations also wheezy and often unattended with marked laryngeal noise, and these are repeated in rapid succession until the patient appears on the eve of suffocation, when probably he is relieved by the discharge of a little mucus.

The *noises* which attend the acts of coughing have already been partly considered. They may be divided into those of the inspiratory act and those of expiration. As regards the former, if there be spasmodic

closure of the glottis, there is either a whoop, as in pertussis, or a whistle, as in spasmodic croup; but if the laryngeal orifice be obstructed by the presence of a false membrane upon it, or if there be an impediment in the trachea, the sound of inspiration becomes wheezy or harsh. In the majority of cases the sound of inspiration is merely that of a deep-drawn breath. The sounds which attend the expiratory element of the cough are due to the condition of the laryngeal orifice and the force with which the expiratory blast bursts through it. Thus if there be no impediment to the full inflation of the lungs, and the vocal cords be in a normal condition, the expiratory acts will necessarily (if forcible) be more or less noisy and at the same time musical. But the character of the sound will of course be modified according to the degree of tension of the cords, and in some measure in accordance with the degree in which they may have become thickened or have lost elasticity in consequence of inflammatory or other change. Many of the most noisy coughs are those which occur in hysterical or nervous patients, in whom the vocal cords are healthy in structure, and in those persons in whom they are affected with only slight catarrh. If, on the other hand, the vocal cords be prevented from vibrating freely, as may happen when the soft parts above the rima are greatly swollen, or the cords themselves and other parts of the larynx are invested with diphtheritic membrane, or laryngeal or tracheal obstruction renders the expiratory blast feeble or insufficient, the cough loses its musical or sonorous character, and becomes wheezy and voiceless.

4. *Expectoration*.—The expectoration is often a valuable aid to diagnosis. Many persons, especially those beyond middle age, spit on rising from bed in the morning a small quantity of viscid or tenacious mucus, studded with black particles. This black matter, which is usually of extraneous origin, is nevertheless contained in cells. Such expectoration indicates the presence of a little bronchorrhœa, but is hardly to be regarded as a sign of any actual disease. In inflammation of the respiratory passages, the discharge of mucus becomes augmented, sometimes enormously. This at first is a watery, slightly viscid, colourless fluid, of saline taste and reaction, containing microscopically shed epithelial cells and mucous and granular corpuscles. Later on its viscosity increases (sometimes it is very viscid from the beginning), it becomes difficult to void, and coalesces after expectoration into a coherent mass, which adheres to the vessel into which it is discharged. Such expectoration is sometimes colourless, sometimes greenish or yellowish, and occasionally streaked with blood. At a still later stage the sputa become opaque and yellow or green, less viscid, and acquire either the physical characters of pus or characters between these and those of mucus. This purulent conversion may be general or partial, and in the latter case the sputa not unfrequently present the so-called 'nummulated' character due to the fact of thick opaque pellets floating in transparent, watery mucus. All these varieties of expectoration may arise in the successive stages of acute or chronic bronchitis: the presence of pure mucus alone indicating for

the most part acuteness of inflammation; that of pus, the supervention of a chronic condition or possibly the approach of convalescence. The nummulated character implies that, while the bronchial tubes are partly secreting mucus, they are partly secreting pus, or pus is gaining an entrance into them from other sources. Nummulated expectoration is frequently met with in cases of dilated tubes, of pulmonary cavities, and of empyematous or other abscesses which communicate with the lung and discharge through it. But it is also met with in simple chronic bronchitis. In many cases, when abscesses open into the lungs, the expectoration consists of almost pure pus. The expectoration of ordinary acute pneumonia is characterised by extreme viscosity with more or less transparency, and by the fact that it is uniformly tinged with blood. Its colour presents numerous gradations between yellow or reddish-brown (rusty) and a bright vermilion. As the disease passes into convalescence, the expectoration loses its peculiar colour and its viscosity, and gets muco-purulent, like that of bronchitis. In certain cases it becomes either distinctly purulent, or, while still incorporated with blood, watery. The latter form of expectoration is sometimes likened to plum-juice.

*Blood* in streaks occurs in bronchitis, blood uniformly diffused in pneumonia; but very often unmixed blood is poured into the bronchial tubes, and is discharged thence, either still unmixed or blended only with a small quantity of mucus. The sources of such pulmonary hemorrhages are the bursting of aneurysms into the air-passages or lung-tissue; the laying open of branches of the pulmonary artery or vein during the progress of tubercle; carcinoma or other destructive morbid processes; intense hyperæmia of bronchial tubes or of the walls of pulmonary cavities; and pulmonary apoplexy. In the last group of cases the hemorrhage is generally scanty; in the others it is often extremely profuse. Copious and sudden hæmoptysis is generally characterised by the

arterial character of the expectorated blood, and by its more or less frothy condition; but when the hemorrhage is small in amount, and expectorated at intervals, it is often in the form of dark-brownish or blackish-red pellets.

*Casts of the air-passages* are not unfrequently expectorated. In diphtheria, membranous casts of various parts of the larynx, trachea, or larger bronchial tubes are often thus discharged. More rarely, branching casts of systems of the smaller bronchial tubes are spat up. These are some-

FIG. 46. CASTS OF AIR-PASSAGES IN PLASTIC BRONCHITIS. Natural size.

times mere coagulated blood, sometimes simple pneumonic exudation concreted in the smaller bronchial tubes, sometimes casts of laminated texture apparently identical with diphtheritic membrane.

Among the *foreign bodies* which are occasionally expectorated must be

mentioned hydatids, either from the lung itself or from the liver, and earthy concretions—the remnants of dried-up tubercular matter in the lungs or bronchial glands. No doubt tubercular, carcinomatous, and other such matters are occasionally brought up, but they can very rarely be recognised as such. The progress, however, of destructive processes in the lungs may often be detected or verified by the discovery on microscopic examination of fragments of lung-tissue. A convenient way of finding these is to boil a small quantity of sputum with a strong solution of caustic soda until they form a thin watery fluid, to place this in a conical glass for the purpose of subsidence, and then to examine the sediment microscopically. The matters to be especially looked for are the curved fragments of elastic tissue which bound the orifices of the smaller bronchial tubes, air-passages, and air-cells. The bacillus of tubercle may generally be readily discovered in the sputum of phthisical patients, even in the very earliest stage of the disease.

*Purulent expectoration* often has a faint, sickly, or sweetish odour. The only smell, however, of clinical importance is that commonly attributed to the presence of gangrene. This is horribly fetid, difficult to describe, but when once smelt impossible to forget. It may be readily detected in the sputum itself; but it is evolved most intensely with the patient's breath during the act of coughing. The sputa which yield this odour are generally distinctly purulent, occasionally nummulated, and have usually a discoloured or dirty-looking aspect. They may be intermixed with blood in a more or less altered condition.

### C. *Investigation by Sight and Touch.*

The information which may be acquired through the eye by inspection, and through the hand by palpation, as to the conditions of those functions of the respiratory system which lie within the scope of such methods of investigation, is obviously very considerable. We will speak of them in relation: first, to the larynx and trachea; second, to the intrathoracic organs.

1. *Larynx and trachea. Laryngoscope.*—The apex of the epiglottis may sometimes be seen, and its condition ascertained, by merely looking into the throat when the mouth is widely opened and the tongue depressed. Its condition, and also that of the parts bounding the upper orifice of the larynx, may sometimes, especially in children, be roughly yet sufficiently determined by means of the tip of the forefinger passed back through the mouth into the fauces. The invention of the laryngoscope, however, and the perfection to which its use has been brought, make it now possible for us to determine the condition of the larynx with the utmost nicety, and to employ local remedial measures with intelligence and accuracy. The apparatus usually employed for laryngoscopic examination comprise: first, a lamp yielding a steady, bright flame, provided with some form of reflector or condenser; second, a circular concave mirror, from 3 to 3½ inches in diameter, and with a focal length of 12 or 14 inches, which should be freely movable in all directions upon

its support, and should either be fixed to the forehead immediately above the eye by means of an elastic band, or attached to a spectacle frame and adapted to the right eye—in the latter case it should be provided with a central perforation of an oval form; third, laryngeal mirrors of metal or silvered glass, of circular, oval or quadrilateral form, and varying in diameter from half an inch, for a young child, up to an inch, fixed each at an angle of about  $120^{\circ}$  to a thin metallic stem or shank, which should itself be fastened into an ivory or wooden handle. The entire length of the combined shank and handle should measure from six to eight inches. In making an examination the patient should be seated in front of the examiner, with his head inclined a little backwards; the lamp should be placed at the side of, and somewhat behind, his head; and the examiner should so arrange himself that his eye, with the mirror adapted, should be at the distance of about a foot in front of the patient's mouth. The mirror should be so adjusted that the light which it reflects may be brought to a focus at about the back of the patient's uvula. He should then be directed to open his mouth widely and to protrude his tongue; the point of which (unless he can keep the organ in a suitable position by voluntary effort) should be firmly grasped and firmly but gently drawn forward by the forefinger and thumb of the operator's left hand, enveloped in a cambric handkerchief or towel, or by the patient himself. Then, the area of reflected light being steadily kept upon the point previously indicated, the laryngeal mirror (which has been previously warmed either over a lamp or by immersion in hot water, in order to prevent the condensation of the patient's breath upon it) is to be carefully passed backward until it reaches the base of the uvula, in which situation it must be held, with its surface facing downwards and forwards, at an angle of about  $45^{\circ}$  with the horizontal plane of the mouth. If the upper orifice of the larynx be not at once seen in the mirror, the direction of the face of the mirror may need a slight alteration, or it may be necessary to pass the mirror a little farther upwards and backwards, or otherwise to modify its position. It is important, in order that the examination be satisfactory: first, that both patient and operator be patient and steady; second, that no needless force be employed to draw the tongue forward, and that it be not injured by undue pressure against the lower teeth; third, that in introducing the mirror, neither the tongue nor the palate be touched by it, excepting of course only that part of the palate against which it has to rest; and fourth, that no single introduction be of long duration. It is best, usually, to repeat the operation several times in the course of a sitting. It need scarcely be added that many difficulties present themselves to interfere with the success of laryngeal inspection, some of which render inspection impossible, while others may be overcome with a little patience and delicacy of manipulation. Excessive irritability of the parts may be counteracted by the local application of cocaine.

Even if the larynx be healthy, we may in some cases perceive only the epiglottis and the tips of the cornicula laryngis. In more successful observations, however, we may detect not only these bodies but all the

other boundaries of the superior orifice of the larynx, including the aryteno-epiglottidean folds, the cartilages of Wrisberg, the posterior commissure, together with the rima glottidis, the true and false vocal cords, and if the rima glottidis be open sometimes the tracheal cartilages, and even the bifurcation of the trachea. All parts of the larynx, except the edge of the epiglottis and the true vocal cords, have a reddish hue, like that of the interior of the mouth, gums, or lips, the redness being usually brightest in the false vocal cords, in the cushion of the epiglottis, and over the cornicula and cartilages of Wrisberg. The vocal cords are pearly-white, the edge of the epiglottis and the tracheal and cricoid cartilages distinctly yellowish.

It is always important to observe the movements of the vocal cords, and to examine the larynx both when the rima is fully open and when it is perfectly closed. The rima is always open during ordinary quiet respiration; but, in order to have it as widely open as possible, the patient should be directed to draw a deep breath. In order to effect closure, he should be required to utter a vocal sound. The best for this purpose, as requiring for their pronunciation the greatest expansion of the oral aperture and cavity, are the vowel sound which is sometimes termed '*ur* vocal,' and is uttered in the words '*cur*' and '*myrrh*,' and the broad sound of '*a*' represented by '*ah*.' Moreover, for obvious reasons he should be directed to phonate in a high key.

The morbid conditions for which we should mainly look are swelling, congestion, ulceration, and exudation, such as may be caused by inflammation, diphtheria, syphilis, or other morbid processes; warty or other growths; paralytic or spasmodic affections of the vocal cords; and compression of the trachea by aneurysmal or other tumours.

As regards the examination of the larynx and trachea from without, the chief points which are ascertainable are: first, the presence of tenderness; second, deviation of the trachea from the middle line, which may be due to tumours either in the neck or within the thorax; and, third, infiltration and thickening of the soft parts around. Thus, in inflammatory affections of the larynx, especially in cases where the cartilages are in a state of necrosis, thickening with induration of the surrounding tissues is often a very remarkable feature; and still more remarkable is the stony induration of parts and the fixation of the larynx which attend some cases of carcinomatous or other malignant infiltration.

2. *Chest*.—The *form* of the chest is often indicative of the presence of disease within. It must not be forgotten, however, that its general form varies widely in different individuals, sometimes from inheritance, sometimes from rickety tendency during early life; and that want of symmetry is often traceable to the preponderating use of the right hand, or to spinal curvature. But such varieties are quite independent of pulmonary affections, and we must be careful not to confuse them with those attributable to the latter causes.

General *expansion* of the chest is a common characteristic of patients who have suffered for many years from chronic bronchitis or asthma,

especially if there be at the same time pulmonary emphysema. Partly in consequence of long-continued over-exertion of the inspiratory muscles, partly from the difficulty which emphysematous lungs have to get rid of their surplus air, the chest increases in both its antero-posterior and its lateral dimensions, and assumes a rounded or 'barrel-like' form. If such changes begin in early infancy, it is not unusual to find that, while the upper part of the chest becomes generally expanded, the lower zone (owing to the comparative weakness of the ribs in early life) undergoes more or less contraction. It is seldom that the causes here spoken of operate on one side of the chest only. General enlargement of one side may be caused by accumulation of serum, pus, or air in the pleural cavity. In such cases the intercostal spaces get widened, the intercostal depressions effaced, and sometimes (especially if the effusion be inflammatory) replaced by actual bulging. Under such circumstances, undulation or fluctuation may occasionally be detected. In cases in which a lung is wholly or in the greater part of its extent pneumonic, the affected side remains fixed in the position of full inflation. Localised enlargements, or bulgings, may be the result of localised accumulations of air or fluid, or of the presence of aneurysmal, sarcomatous, or other varieties of intra-thoracic tumours. In cases of empyema it is not uncommon for the pus to find its way between the ribs, to form an accumulation between them and the integuments, and thus to cause a localised swelling.

*Contraction* of the thoracic walls is exceedingly common; but it is rarely general and symmetrical, unless it be due to natural conformation, or be the consequence of rickets, or of diseases like whooping cough attended with long-continued impediment to inspiration. It is of chief clinical interest when it is unilateral or limited to definite regions. All pulmonary diseases, attended with diminution in the size of the lung, are attended with more or less marked contraction corresponding to that diminution. The most remarkable example is furnished by empyema or hydrothorax which has caused complete and permanent collapse of the lung. With the absorption or removal of the fluid the affected side gets reduced in all its dimensions, but especially flattened from before backwards, and the patient's carriage comes to resemble that of a person suffering from lateral curvature of the spine. Atelectasis, apneumotosis, cirrhosis, and the contraction of cavities are all attended with more or less manifest contraction of that area of the chest-wall which corresponds to the portion of lung involved; but the most frequent, and on the whole the most important, of these localised contractions is that so commonly observed beneath one or both clavicles during the progress of phthisis.

The *movements* of the chest are often very significant. The violent muscular efforts, yet little movement of the ribs, which mark the respiratory acts of emphysematous patients with barrel-shaped chests are very characteristic. The entire quiescence or little comparative movement of the affected side in cases of effusion into the pleura or of pneumonic consolidation, and of the apex of the lung in cases of phthisis, is equally matter of interest and clinical importance.

Whenever grave notes are uttered by the voice a distinct vibratile thrill, the *vocal fremitus*, may be felt, not only over the larynx and trachea, but over the face and head, and over the whole of the surface of the chest to which lung-tissue is subjacent. The best mode of detecting this thrill in the chest is to place the palm of the hand flat and firmly on the part selected for examination. The degree in which it may be perceptible varies greatly in different persons, in dependence partly on the pitch and strength of the voice, partly on the quantity of muscle or fat present in the parietes of the chest. It is generally best recognised in male adults with spare frames. For obvious reasons it is more perceptible at the upper part of the chest, in front and between the scapulae, than elsewhere; and it is either absent from the area of cardiac dulness, or comparatively feeble there. It is said to be a little more marked on the right than on the left side of the chest; but the difference is at most trivial, and it may be regarded as a general rule that, with the exceptions referred to, it is equal in degree at all corresponding parts of the two sides of the chest. The presence of disease largely modifies the intensity and distribution of the vocal fremitus. Whenever there is fluid effusion into the chest, the thrill becomes greatly enfeebled or absolutely annulled over the surface corresponding to the fluid. Whenever, on the other hand, lung-tissue is consolidated by pneumonia, the vocal fremitus over the affected region is much intensified. It must be added that mere thickening of pleura, or accumulation of solid lymph in its cavity, acts equally with fluid effusion in damping vocal fremitus; that solid growths, whether in the lung or external to it, have a like effect; and that in rare cases fremitus is diminished even over pneumonic lung. The explanation of the diminution of vocal fremitus in the several cases above enumerated is sufficiently obvious. The intensification which attends most cases of pneumonia is due apparently to the concurrence of two conditions: the one, consolidation of the vesicular tissue which increases its capability of conducting sounds; the other the permeation of the solid mass by pervious tubes along which the vocal vibrations are carried into its midst.

In the act of coughing an impulse or shock is conveyed to the hand placed upon those parts of the chest which are in direct relation with lung. This shock, like vocal fremitus, is diminished by pleural effusion and increased by pneumonic consolidation. But it is specially increased over cavities, pulmonary or pleural, which abut on the surface and are in free communication with tubes. The explanation is simple. At the moment at which the expiratory shock of a cough is taking place, the glottis is closed, the expiratory muscles are acting violently, and there is a sudden rise of pressure due to the imprisoned air throughout the bronchial tubes and cavities connected with them; the percussive effect of which at the pleural surface of any cavity, and consequently on the thoracic parietes over it, must necessarily be greater the larger the unsupported area on which it acts.

In support or correction of the judgments formed from the results of visual or manual examination, it is always well to have recourse to actual

measurement of the chest, or of portions of it, and of the amount of expansion or movement which they undergo. It is needless to describe in detail how all such measurements are to be effected; it is sufficient, probably, to name the chief instruments which may be used for the purpose, the measuring-tape and calipers and the cyrtometer.

The last name is applied to a metal wire, or specially devised band, which admits of close adaptation to the surface of the chest, and retains its form after removal, so as to allow of a tracing being made from it.

*Spirometer.*—It is sometimes useful to ascertain what Dr. Hutchinson calls the ‘vital capacity’ of the chest by means of an instrument made on the principle of the gasometer, which he terms the ‘spirometer.’ He measures this capacity by the amount of air which a person who has distended his chest to the utmost is able to discharge by voluntary expiratory effort. This amount appears to be very constant in relation to stature. Thus, the average vital capacity of a man five feet seven inches high is about 225 cubic inches, and for each inch of stature above this there is an increase, and for each inch below it a decrease, of about eight cubic inches. It is often difficult to make persons under examination exert a sufficient effort to manifest their true vital capacity; but if after having done so there is any wide departure from the scale above given there is good reason to suspect the existence of some morbid condition, either involving the lungs, or interfering with the due performance of the respiratory acts. The vital capacity of women is much less than that of men.

#### D. *Investigation by Percussion and Auscultation.*

Of all aids to the recognition of the morbid processes which are going on within the thorax none is so important as the employment of *percussion* and *auscultation*: both, methods of investigation scarcely thought of prior to the commencement of the present century, but which, since that period, have been largely cultivated and have furnished the most valuable results both to the physiologist and to the physician.

1. By *percussion* is meant the investigation of the condition of internal organs by the sounds which are yielded by sharply striking the surfaces over them. There are three principal methods by which this may be effected, namely: 1st, by striking the surface directly either with the fist, the knuckles, or the tips of two or three fingers brought together into the form of a hammer, or by simply filipping with the nail of the forefinger; 2nd, by the use of the hammer and pleximeter (the pleximeter is a small thin ivory disc, which, for the purpose of receiving the blow of the hammer, has to be laid firmly and flat upon the surface of the part to be percussed; the hammer, which usually has a comparatively heavy metallic head, is furnished at its striking extremity with an india-rubber pad, which alone comes in contact with the pleximeter, and prevents the development of any sound special to the instrument); 3rd, by the employment of the fore or middle finger of the left hand as a pleximeter, and the tips of one, two, or three fingers of the right hand as a hammer (in this case the finger of the left hand should be laid firmly and flat, with its palmar surface down-

wards on the surface to be examined, and the tips of the striking fingers of the opposite hand should be brought down perpendicularly and sharply upon it). The first of these three methods of percussion has fallen into almost entire disuse, chiefly because of the needless pain which it is apt to inflict; still it may sometimes be employed with great advantage (and especially the method of filliping with the forefinger), when, as in the chests of young children, and in the exploration of the abdomen, even slight pressure of the pleximeter is liable to displace air or fluid, the presence or absence of which at some particular point it is important to determine. The second method is a valuable one, especially for clinical teaching, because the sounds which it evolves are loud and readily distinguishable by a class of students. The third method is that which is in general use, partly because of its great convenience, and partly because, although the sounds which are evoked by it are comparatively feeble, they are perfectly appreciable. Whenever it is sought to compare by percussion the corresponding parts of opposite sides of the trunk, it is most important that for each pair of examinations the pleximeter, whether the finger or the disc, should be symmetrically placed, and the force and direction of the blows should correspond. Further, it is important as far as possible to prevent any sound due to the instrument itself from interfering with that elicited from the part percussed.

a. *Normal percussion phenomena*.—The sounds yielded to percussion by the healthy chest are of two kinds, *resonant* and *dull*. These words are by no means well chosen, but they are sanctioned by long and general usage, and would be difficult to replace. By resonance we mean to imply the presence of more or less musical quality, by dulness the absence of such quality.

i. *Resonance*.—A resonant sound is yielded by all those parts of the chest-walls which are by their deep aspect in contact with lung, and by that part of the left half of the chest to which the stomach is subjacent. The quality of the resonant sound which is evolved on percussing the pulmonary regions of the thorax is difficult to describe, but sufficiently characteristic to be easy of recognition when once it has been heard. It is somewhat deep in tone, short in duration, and vaguely musical. It differs, however, in some degree in quality in different parts of the chest, and considerably in different individuals. Hence it is important, in judging of the significance of percussion-sounds, not to assume the existence of a normal standard-sound with which all others must be compared, not to compare the resonance of one person's chest with that of another's, nor, indeed, to compare indiscriminately the resonance of different parts of the same individual's chest. But we should carefully compare the sounds yielded by the corresponding points of the two sides of the chest. The chief cause of the resonant quality of the percussion note is the vibration of the struck walls which is permitted by the fact that an elastic medium (the air) is situated on either side of them. It is obvious, however, that the elasticity of the inflated lungs is less than that of the free atmosphere outside, and that hence the vibration of the thoracic walls

must be to some extent less perfect than it would be were the air on both sides equally free to move. The sound, we repeat, is mainly due to the vibration of the thoracic walls alone; but it is difficult (owing to the somewhat irregular form and structure of these walls and to the interference with their vibration caused, on the one hand, by the solid organs which lie here and there beneath them, and, on the other hand, by the junctions of the chest with the upper extremities) to determine to what extent and in what manner these vibrations are effected. It seems reasonable, however, to assume that so much of each half of the thorax as bounds lung-tissue vibrates bell-like when any part of that half is struck, and that the impure musical sound which is elicited comprises a fundamental note due to the vibration of the whole or a large portion of the side, and harmonic tones due to the vibration of aliquot parts of it. This view is entirely compatible with the fact that percussion notes of somewhat different quality are yielded on striking different parts of the surface, and, if correct, makes it obvious that the sound obtained by the percussion of any spot is by no means necessarily indicative of the condition of the lung-tissue immediately beneath it. Some, though a very variable proportion of thoracic resonance is independent of the presence of air beneath the chest-walls. Thin and elastic bones, even if they be imbedded in solid tissue, vibrate sensibly when percussed. A sound which is not absolutely dull may be obtained by percussing the bones of the skull; and some degree of resonance may always be elicited over the sternum even when no lung-tissue is beneath it. The ribs, also, especially if the patient be thin, usually yield a somewhat resonant sound.

The stomachal resonance may always be recognised (though variable in extent, distinctness, and quality according to the degree of distension of the organ with gas and to the level which it attains within the cavity of the thorax) at the lower part of the left side of the chest, both posteriorly, laterally, and in front, but chiefly in the last two situations. It may readily be distinguished from the normal lung-resonance by its much more distinctly musical character, by its purer tone and generally higher pitch. The sound is often termed *tympanitic*, or drum-like.

ii. *Dulness*.—Absence of resonance, or dulness, is observable on percussing the præcordial region, and that part of the right side of the chest between which and the liver no lung-tissue intrudes. This sound, again, can be better appreciated by a single experiment than by any description. It may be described as short, somewhat sharp, and unattended with any appreciable ring or tone. The feeble sound elicited by the percussion of the thigh is often referred to as the very type of a so-called ‘dull’ sound. It differs, however, materially from that which is yielded by the præcordial region. And, indeed, the quality of dulness, in the clinical sense, presents many varieties, and passes by insensible gradations into that of resonance. Many so-called dull sounds become obviously musical when tested stethoscopically.

b. *Abnormal percussion phenomena*.—Percussion in cases of pulmonary disease is mainly of use in enabling us to ascertain the presence and define

the limits of consolidation, pleural effusion, and morbid growths, and of conditions causing extension or modification of resonance.

i. *Dulness*.—Whenever any considerable mass of lung-tissue is rendered solid, either by tubercular infiltration, by inflammatory deposit, by effusion of blood, by carcinomatous growth, or in any other way, all that area of the chest-wall on which it abuts loses its normal resonance and becomes more or less dull. The presence of fluid in the pleura causes dulness in even a more marked degree up to the level of the effusion. The recognition of the cause of dulness must depend partly on the situation, extent, and form of the area of dulness, partly on a variety of considerations, the collective significance of which will be more conveniently discussed hereafter. It may be mentioned, however, that pneumonic consolidation usually occurs in the lower part of the lung, tubercular infiltration at the apex, and that pleuritic effusion, unless it be circumscribed by adhesions, or so abundant as entirely to compress the lung, may often be recognised by the changing level of the upper limit of dulness in accordance with the different positions which the patient's trunk is made to assume. But although marked dulness is always present when consolidation is extensive and continuous, it is often absent, or at all events scarcely appreciable, when either an extensive tract of lung-tissue uniformly contains more solid matter or fluid and less air than natural, or miliary or larger nodules of solid substance separated from one another by a network of crepitant tissue are even thickly distributed. Thus congested or œdematous lungs, and lungs in the early stage of inflammation, on the one hand, and lungs which are the seat of disseminated tubercles or of lobular pneumonia on the other, are not unfrequently so strikingly resonant as utterly to deceive the too confiding percusser.

ii. *Resonance*.—It is obvious that, whenever there is any extension of the area of dulness, there must be a corresponding diminution in the area of resonance. On the other hand, the normal areas of thoracic dulness are not very unfrequently reduced or effaced by the extension of resonance. In association with such changes, and sometimes indeed apart from them, the resonance of the resonant area is altered in intensity, quality, or pitch. To denote different varieties and degrees of resonance many terms have been employed—as, for example, wooden, leather-trunk-like, tubular, cavernous, tympanitic, high-pitched, and the like. Some of these are obviously fanciful, some indicative of a foregone conclusion with regard to the case under examination; but others do, to some extent, explain themselves, are applicable and convenient. Augmentation of resonance (to which condition the epithet *tympanitic* is sometimes given) may often be heard over emphysematous lungs, or lungs distended (as they sometimes are in cases of acute bronchitis) with air, but especially over a pleural cavity the seat of pneumothorax. In such cases, however, the augmentation of resonance is for the most part attended with the production of a purer note, and frequently a note of somewhat higher pitch, than characterises the normal chest-resonance of the patient. But augmented resonance with change of quality and pitch is often heard under

very different conditions from those just considered. It is frequently observed, for example, that in cases of extensive pulmonary consolidation, or pleural effusion, of one side, the crepitant remnant of lung-tissue evolves under percussion a much purer note than the corresponding part of the opposite lung. The sound is sometimes described as being more resonant than that yielded by the opposite side; possibly it may be so, but it is at all events more distinctly musical, and always of considerably heightened pitch. Not unfrequently indeed the sound is almost exactly like that produced by percussing a portion of small intestine, or striking one of the treble keys of the piano. This modified resonance is most frequently observed over the apex of the lung when the rest of the organ is consolidated or compressed; but by no means necessarily occurs only in that region; and may sometimes be distinctly heard over portions of pneumonic lung which are not yet completely solidified. Various explanations of the phenomena here described have been given. With respect to the increased resonance which attends pneumothorax, emphysema, and the like, it will probably be admitted that it is due to the more ready and perfect vibration of the thoracic walls which the relative increase of air beneath their inner surface permits. This explanation, however, will scarcely apply to the higher pitch which the percussion note usually then acquires, and is certainly not applicable to those cases in which high-pitched resonance occurs over partly consolidated lung, or lung in the neighbourhood of consolidated tissue. Reverting to the explanation we have already given of the ordinary resonant sound yielded by the thoracic walls (namely, that in its production all those parts of the thoracic walls which are in contact with the lung under examination vibrate, bell-like, producing a somewhat obscure assemblage of fundamental and harmonic tones, the general effect of which is deep in some sort of proportion to the extent of surface which vibrates); and knowing that (other things being equal) the smaller a vibrating area becomes the higher will be the fundamental tone it yields; and seeing that such a diminution of vibrating area necessarily takes place when there is extensive consolidation or fluid effusion, and not improbably occurs in the first stage of pneumonia over the affected portion of lung; it seems reasonable to assume that mainly in these considerations is to be sought the explanation of the acoustic phenomenon in question. It must not be forgotten, however, that the increase of tension, which in pneumothorax, and in a less degree in pleurisy with effusion, the thoracic walls experience, also tends to the production of a higher note.

The question 'how far can the percussion note be modified by conditions within the chest other than those which have been discussed?' still remains for consideration. Can it, for example, be affected by the neighbourhood of solid matter separated from the parietes by a layer of crepitant tissue? Can it be modified by the internal resonance of cavities which abut upon the surface? The former of these questions has been answered in the affirmative by most writers; who assert that, by regulating the force of the percussion stroke, the resonance due to the

intervening lung and the dulness due to the subjacent solid structure can be distinguished, and that thus the extension of the heart beneath the thin edge of the lung, and the ascent of the liver behind the lower margin of the right lung, can be easily detected. We confess we are not satisfied of the general truth of this assertion. We may remark, however, as bearing upon it: that the quality and power of a musical tone differ according to the part of a vibrating cord or surface which is struck, and that hence the quality and power of percussion tones are doubtless modified as we pass from the centre of a resonant area to its margins; and again that it is quite possible in the yielding chests of young children, if undue pressure be made by the pleximeter, to compress or displace the thin edge of the lung lying between the heart or liver and the parietes, and so to obtain dulness, where normally resonance should be elicited. But this is the consequence of pressure and not of percussion. As to the latter of these questions, there is no doubt that, if auscultation be practised at the same time as percussion, the resonance due to a subjacent large cavity may occasionally be recognised in the form of a superadded musical twang. There is, however, one variety of percussion sound which certainly owes its peculiarity to the conjunction of a sound produced within the chest with that due to the vibration of the thoracic walls, namely, the *bruit de pot fêlé*, or cracked-pot sound—a sound which may be almost exactly simulated by clasping the hands crosswise and then striking the back of one of them sharply against the knee-cap. The ‘chink’ which distinguishes it appears to be due to the sudden compression of a portion of lung-tissue and the sharp expulsion of the air which it contained with an audible hiss through the bronchial tubes. To produce the sound the percussion stroke must be forcible, and should be made while the patient is expiring with his mouth open. It is chiefly producible in the front of the chest, either at the apex or in the mammary region. It may indicate the presence of a cavity in the lung, but is more commonly produced in the healthy chests of young children owing to the great yieldingness of their thin thoracic parietes, and in patients suffering from pneumonia or pleurisy in association with the high-pitched resonance so often present.

c. *Resistance*.—One further indication of importance often furnished by percussion is the presence of unyieldingness or resistance. In the percussion of healthy chests the resilience of the parietes can always be in some degree appreciated; it is indeed so constant and essential a factor of the process that on that very account it may escape observation. But in cases of solid growths in the cavity of the thorax, and in cases even of pleurisy with much thickening of pleura and much distension, the rigidity of the thoracic walls over some limited area, and their total want of elasticity and of yieldingness, are quite remarkable and unmistakable.

2. By *auscultation* is meant the process of listening, either by applying the ear directly to the surface, or by the aid of some conductor, to sounds evolved within the body. The direct application of the <sup>ear</sup> ~~an~~ to the surface is in some respects preferable to any other mode of auscultation. Many

sounds are thus heard much more distinctly than they otherwise would be heard; and some delicate but distinctive sounds are wholly lost in their passage along a conducting rod or tube. But, on the other hand, the naked ear cannot be applied with ease to all parts which it is desirable to auscultate, nor can we by its aid limit our examination with precision to minute *areæ*. The objections on the score of delicacy and cleanliness are sufficiently obvious.

The instrument which is employed to convey sounds produced within the body to the ear of the observer is termed the *stethoscope*. Of this innumerable forms and varieties have been invented and are in use. As to material, they have been made of bone, ivory, silver, gun-metal, gutta-percha, and different kinds of wood; as to form, they are always cylindrical in the whole or greater part of their extent—in the latter case being provided at one end with a circular disc to fit the ear, at the other end with a conical expansion, the circular base of which is to be applied to the part under examination. Further, they are made of different lengths, sometimes solid throughout, but generally with a cylindrical channel running through the stem from the ear-piece downwards to the conical enlargement, where it undergoes a corresponding dilatation. The material, the length, and the general form of the instrument are matters of very little real importance. The great desiderata are that it should be light and portable, that the ear-piece should be one that readily adapts itself to the ear of its possessor, and that the conical enlargement at the opposite end should be of medium size, and (if provided with an opening) its margin sufficiently broad and rounded to admit of its adjustment without causing pain.

There are certain peculiarities in the acoustic properties of stethoscopes which it is well to be aware of. Solid stethoscopes undoubtedly convey sharp impulsive sounds and musical notes with great intensity; but they do not transmit the respiratory rustles and other feeble and unmusical sounds with anything like the distinctness with which the hollow stethoscope conveys them. The difference is very much that existing between a speaking-tube which readily transmits the whispered voice, and a solid rod which, with the aid of a sounding-board, reproduces at a distance the full music of a piano with which its opposite extremity is in contact. The hollow stethoscope, however, combines in itself the properties of both, and is therefore the preferable instrument for common use. Again, it is indisputable that certain sounds are much more distinctly audible with some hollow stethoscopes than others; and that this fact is, in some instances, due to differences in the length of the instruments. The explanation appears to be that the tubes of stethoscopes *consonate*, according to their length, with certain definite notes and certain of their harmonics.

Besides the simple varieties of stethoscope above considered, there are two others which are often of considerable service. These are the *binaural* and the *differential* stethoscopes. In the former, the stem arising from the conical end divides into two branches, the points of which respectively fit into either ear. Both ears are thus equally engaged in listening to the

sounds emanating from the area under examination, which are hence intensified and on the whole more easily appreciated. The other form of stethoscope is also binaural in the sense that there is an ear-piece for each ear, and both ears are engaged; but the tubes which are prolonged from the ear-pieces remain distinct from one another and terminate each in a conical expansion. The advantage of this arrangement is that by it the auscultator is enabled to hear and determine the synchronism or asynchronism of sounds which are developed at different spots.

In using the stethoscope it is of essential importance that (if it be hollow) its lower end should rest evenly on the surface to which it is applied, that the ear-piece should be adjusted accurately to the ear, that nothing whatever should be in contact with the instrument save the ear of the auscultator and the surface under examination, and that there should be no rustling or friction or other noises in connection with the patient's skin or clothes. It is always best to listen to the naked skin; and, if covering be necessary, it should be as thin as possible and in one layer only. Further, it is sometimes well to close the opposite ear against extraneous sounds.

*a. Normal auscultatory phenomena.*—The sounds audible through the stethoscope applied over the healthy respiratory organs are those of respiration, articulation, and phonation. In morbid conditions of these parts, the acoustic phenomena attending the several acts referred to become variously and often largely modified, and others of a totally different kind are often superadded.

*i. Auscultation of the breath.*—If we apply the stethoscope to the larynx or trachea during ordinary respiration, a somewhat harsh blowing sound is heard to accompany both the act of inspiration and that of expiration. The sound is like that of the loudly-whispered vowel represented by the syllable 'ur,' or like the whispered consonantal sound of the letter *w*. Each sound lasts as long as the act which produces it, is uniform in character throughout, begins and ends abruptly, and is separated by an obvious though very short interval from the sound which follows it. That attending inspiration is somewhat sharper and louder than the other, and both may be increased or diminished in intensity by varying the force of the respiratory movements. The sounds are almost certainly developed at the narrowest part of the tube, namely, the rima glottidis, by the rustle which its interference causes in the current of air passing through it. The slight but obvious differences in quality and force which distinguish them from one another are hence explicable; the sound produced at the rima being carried inwards with the inspiratory current, outwards during expiration. Ordinarily, the sound attending expiration is more audible to oneself and to bystanders than that attending inspiration. The sounds here described, though somewhat modified in character, are in general still audible over the manubrium of the sternum, and between the scapulæ, at and above the level of the roots of the lungs.

Over the lungs themselves the sounds which attend the respiratory

movements are of a very different character from the above. The inspiratory sound is difficult to describe : it has a kind of rustling character, and is feebler and of lower pitch than the corresponding tracheal murmur ; the expiratory sound is often absent, and when present is still feebler and lower in tone than the inspiratory sound. Moreover, the two sounds, instead of presenting uniform intensity throughout, and being separated by a distinct interval from one another, commence and die away so gradually that they seem like mere pulses of a continuous murmur. The healthy pulmonary sounds vary a good deal in intensity, and, in some degree, in quality in different individuals ; there are also slight differences between them as heard at different parts of the same chest ; and not unfrequently, especially at the apex, the sound towards the end of a deep inspiration assumes an indistinctly crepitating character. What is the cause of these sounds ? That they are not made in the larger air-passages, and conveyed through the spongy tissue of the lungs to the surface, seems clear from the fact that in those cases where, from contraction of the larynx, trachea, or bronchial tubes (as in laryngitis, pressure of an aneurysm, and asthma), a peculiarly intense noise is made in these canals during respiration, the pulmonary murmurs, instead of being correspondingly augmented, are diminished or actually suppressed. The ordinary explanation is doubtless the correct one, namely, that they are produced in the minuter air-passages and air-cells by the passage of air to and fro in them, and by the changes of form—the movements— which these parts undergo.

ii. *In auscultating the voice* it is important to recollect the fact that phonation takes place (the music of the voice is manufactured) at the rima glottidis by the vocal cords ; that articulate sounds are formed only in the cavity of the mouth, by means, chiefly, of the lips, tongue, and palate. If the larynx or trachea be examined stethoscopically during the act of speaking aloud or singing, the musical notes which are evolved are conveyed through the instrument to the ear with almost painful force ; similar sounds, diminished somewhat in intensity, are also audible over the manubrium of the sternum and between the upper parts of the scapulæ behind. They are still audible, but with much less force, over the whole of those portions of the chest which have lung-tissue beneath them. The sounds are usually somewhat more intense above than below, in front than behind, and at the lower part posteriorly sometimes present, even in health, a somewhat bleating character. The degree in which vocal resonance or *bronchophony* is audible varies in different individuals, chiefly in dependence on the pitch and quality of the voice. Thus it is, as a rule, more obvious in those who have a deep voice than in those whose voice is high, and in men therefore than in women or children. It is often distinct when vocal fremitus is quite imperceptible, and in some individuals scarcely exists at all. The articulate voice is always best distinguished when the patient speaks in a whisper : words thus uttered are distinctly transmitted through the stethoscope applied to the windpipe in the neck, or along its course in the thorax, or over the situation of the

bronchi; they may also occasionally be heard over the apices of the lungs of healthy persons, especially children. When actual words can be distinguished through the stethoscope we have the phenomenon to which the term *pectoriloquy* is properly applied.

*b. Abnormal auscultatory phenomena.*—The respiratory sounds are often much modified in disease. We have adverted to the fact that they are frequently not only greatly diminished, but actually absent, in certain cases of obstructive disease of the larger air-passages; they are enfeebled also whenever the respiratory movements are themselves feeble, and are generally much weakened or even annulled where the lung is compressed, consolidated, displaced, or where fluid, air, or solid matter lies between it and the thoracic walls. On the other hand, the respiratory sounds are necessarily intensified whenever the acts which produce them are unusually vigorous. It is due, doubtless, to this cause alone that they may often be heard with preternatural loudness over the healthy lung of a patient whose other lung is pneumonic or compressed by pleural effusion.

*i. Tubular or bronchial breathing* is a modification of respiratory sound frequently heard over lungs consolidated by pneumonia, compressed by pleuritic effusion, or containing smallish cavities, of whatever origin, imbedded in airless tissue. It almost exactly resembles the breath-sounds audible over the trachea. The inspiratory and expiratory elements begin and end abruptly, are uniform throughout, and separated from one another by a distinct but short interval; moreover, the expiratory sound is somewhat deeper and less distinct than that of inspiration. They vary in quality in different cases and under different circumstances, but are generally higher in pitch than the tracheal sounds are. It is necessary, in order to their full development, that the respiratory acts be moderately forcible, that the air-tubes of the portion of lung under examination be not completely obstructed, and that they do not contain mucus or other matters which are productive of crepitating and other such adventitious sounds. Hence, in pneumonia, tubular breathing may be absent or incapable of recognition if the bronchia be blocked up with casts; in pleurisy, if the compression of the lung be so great as to involve the obliteration of the tubes; in pulmonary excavation, if the vomiceæ have no free connection with the air-channels; and in all such affections when the cavities or tubes are loaded with mucus or other fluids. Various explanations have been offered of the production of tubular breathing. By some it has been held that the sounds heard over the affected portion of lung are simply those manufactured at the rima glottidis, conducted to the ear through the diseased tissues.<sup>1</sup> Others consider that the tubular sounds are actually produced by the to-and-fro movement of air in the tubes of the diseased tract. While others, as Skoda, regard them as the laryngeal sounds increased and modified by consonance in the bronchial tubes. Dr. J. F. Bullar<sup>1</sup> has shown experimentally that sounds exactly like those of tubular breathing are developed in the tubes of a motionless lung, or motionless bit of lung, when the other lung or the other

<sup>1</sup> *Proceedings of the Royal Society*, No. 234, 1884.

portion of lung is executing respiratory movements, and he attributes them to the influence of the air in its passage to and from the breathing lung on the stagnant air of the tubes belonging to the inactive lung-tissue, on the principle that air blown across the orifice of a tube produces acoustic vibrations in the tube. An insuperable objection, it seems to us, to the truth of Skoda's explanation is the fact that consonance either increases the intensity of obvious musical tones, or develops an obvious musical tone from unmusical sounds or from vibrations which are musical in rhythm, but of themselves too feeble for the ear distinctly to appreciate. But the tubular sounds heard over a pneumonic lung are no more musical than those heard over the trachea. An objection to the second explanation resides in the fact that, in the majority of cases in which tubular breathing is heard, the affected lung-tissue neither expands nor contracts during respiration, so that there can be no to-and-fro movement of air in its tubes to cause the sounds which may be heard over it. The first explanation has much to commend it, for the sounds of tubular breathing are much like those produced at the rima glottidis during respiration; there is no doubt whatever that these, as well as all other sounds developed at this orifice, are readily conveyed, with little change of character, along the patent bronchial tubes, as along so many small stethoscopes, towards their peripheral distribution; the intensity of the tubular sound is proportionate, in great measure, to the intensity of the laryngeal sound, and indeed a distinctly tubular sound may, even in health, be developed and actually overpower the normal respiratory sounds when patients who are told to breathe deeply breathe noisily through the larynx. On the whole, however, we are inclined to accept Dr. Bullar's as a sufficient, if not the only, explanation of the phenomenon. It seems to be in accordance with the circumstances under which tubular breathing is observed, and explains the slight but obvious differences of quality presented by tubular breathing in different cases more satisfactorily than any other hypothesis. Whatever explanation be adopted, however, there is no doubt that the homogeneousness of texture which a consolidated or compressed lung presents allows, far more readily than normal spongy lung-tissue does, of the transmission of sounds which are developed within or conveyed into its substance; and further, that the total suppression of the healthy respiratory murmur, which characterises all those conditions of lung in which tubular breathing is heard, contributes importantly to its ready recognition.

ii. *Amphoric, cavernous or metallic breathing.*—These terms are employed to designate the peculiar quality of sound which may sometimes be heard over cavities containing air, and usually communicating with the external atmosphere by means of the bronchial tubes or other passages. It consists in a peculiar metallic ring, or musical twang, following upon the respiratory or other sound which calls it forth. A closely similar twang attends the footfall of a person walking between high walls, or over a vault, and may be recognised in perfection if a child's india-rubber ball be placed in contact with the ear, and then sharply tapped or filiped.

The addition to any other intrathoracic sound of the musical prolongation here referred to is always indicative of the presence of a cavity containing air; and it may sometimes be heard almost as distinctly in a cavity the size of a walnut as in one corresponding in capacity to the whole of the pleural sac. Its presence does not absolutely prove that there is communication between the cavity and the outer air, although in the great majority of cases such a communication does in fact exist; nor does it prove that the cavity to which it is due is an abnormal cavity, for it may, when detected at the lower part of the left side of the chest, be referrible to the stomach; nor, again, does it necessarily throw light on the form of the cavity or the structure of the walls, although, for the most part, we have reason to suspect when we hear it that the cavity or some part of it is of a rounded form, and that the walls are somewhat smooth and elastic, or, at all events, of such a character as to allow of reverberation. The cause of this amphoric resonance is obviously the reverberation, or succession of echoes which occurs between the opposite sides of the cavity when any impulse or sound capable of originating it reaches the air in its interior. The chief conditions under which amphoric resonance manifests itself in connection with cavities are the following:—First, it attends the respiratory sounds, and more particularly that of inspiration. It is important, however, to observe that the respiratory sounds yielded from a cavity are, apart from the superadded resonance, tubular; and that if, from any circumstance, the musical twang be absent from them, there is nothing left by which they can be distinguished from ordinary tubular breathing. It is probably never produced in this case unless the cavity communicates with a bronchial tube or by a fistulous opening with the external air; and although it is probably not essential to its production that there shall be actual movement of air into and out of the cavity, there is no doubt that such movement tends largely to intensify it. Second, it attends both the sounds of vocalisation and those of coughing. Third, it may be evolved over large cavities by percussion of the thoracic walls which bound them, and especially if the percussion sound be sharp and short, as it may be made by employing two coins—one as a pleximeter, the other as a hammer (*bruit d'airain*). Fourth, it gives a metallic quality to the various râles or rattles which are produced in them or in their vicinity by the passage of air through fluid. It should be noted, however, that short sharp sounds like those of ordinary largish crepitation more readily induce an audible echo than do the duller less intense sounds of respiration and the like; and that hence crepitation often becomes metallic in small cavities, which give no such quality to respiratory, vocal, or tussive sounds, and sometimes even in the normal cavities of the bronchial tubes. Lastly, in large cavities we not unfrequently get that perfection of amphoric resonance which is termed *metallic tinkling*; a sound which is always most characteristically evolved in response to some sharp detonation, such as is produced by the bursting of a largish bubble or by the fall of a drop of fluid from above on to a surface of fluid below.

The cavernous echo, although in many cases remarkably distinct and unmistakable, is in some cases so feeble that it fails to be transmitted along the ordinary stethoscope, and can be detected only by aid of the binaural stethoscope or by the ear applied directly to the chest. Further, it may be, and often is, effectually concealed by the intervention between the cavity and the thoracic walls of a layer, however thin, of crepitant lung-tissue. And, again, it is important to know that cavities of considerable size, especially if there be no communication, or only imperfect communication, between them and bronchial tubes, often yield no sound whatever due to themselves, and merely very feebly conduct tubular or even healthy respiratory sounds due to the lung-tissue in which they are imbedded.

There are yet one or two other sounds which may be developed within cavities, and may hence be included within the meaning of the term *cavernous respiration*. It is possible, for instance, that a cavity may be of such a size and shape as to be capable of resonating to some particular note; and that the production of that note by the patient in his larynx may be attended with special resonance within the cavity. And, again, it sometimes happens that when a cavity communicates, by a flap-like or valvular opening, with a bronchial tube, there is no sound audible over the cavity during ordinary respiration or during the earlier period of a forcible inspiration; but that during the course of the latter the air rushes into the cavity with an audible click, hiss, or gurgling sound—a phenomenon which is repeated whenever the patient inspires deeply.

iii. *Bronchophony, pectoriloquy, and egophony*.—The terms pectoriloquy and bronchophony have been employed with great laxity, even by those who assume to be authorities upon the subject of auscultation. It has frequently been asserted that bronchophony as it becomes more marked passes into pectoriloquy, as though the two conditions were mere grades of the same phenomenon. This, however, is certainly not the fact; bronchophony never becomes converted into pectoriloquy, although they are often associated; loud bronchophony, indeed, drowns the pectoriloquy with which it may be associated; and, in order to be certain of the existence of pectoriloquy, it is always best to eliminate the effects of bronchophony by making the patient speak in a whisper. As we have already pointed out, bronchophony is the offspring of laryngeal intonation, pectoriloquy of the articulate sounds developed within the cavity of the mouth.

*Bronchophony*, in its pathological sense, means preternatural distinctness, or loudness, with little alteration of quality, of the laryngeal musical tones as conveyed to the ear through the tissue of the lung. Its intensity, as well in disease as in health, presents considerable variety. Hence in determining the presence or absence of abnormal bronchophony we must not be content to note that the voice-resonance is louder in one part than another; but we must observe whether it is relatively loudest over those parts of a lung in which normally it is comparatively feeble; and especially we must be careful to compare the resonance of the voice in corresponding parts of the two sides of the chest. Bronchophony is

generally developed over consolidated lung-tissue (pneumonic, tubercular, or other) and over the sites of vomicæ. And its development in abnormal situations is clearly due to the same combination of causes as that to which we have ascribed the phenomena of tubular breathing :—namely, first, the conduction of the musical vibrations along the patent bronchial tubes, or tubes and cavities, into the very substance of the consolidated tissue ; and, second, the ready transmission of these vibrations thence through this tissue to the surface of the chest. Skoda attributes bronchophony, as he does tubular sounds, to consonance of the laryngeal sounds within the bronchial tubes. We are far from denying that the tubes may consonate to musical sounds, or that they do so consonate in certain cases. But a tube of a certain definite length can only consonate to a certain definite note, and possibly to some of the higher harmonics of that note ; and assuming (what seems scarcely possible) that the length of tube capable of consonating is to be measured from the rima glottidis to the terminal part of a bronchial tube at the base of the lung (a length of about twelve inches), the lowest note to which it (being a pipe closed at both ends) could consonate would be one produced by undulations a foot long, or one lying between B and C of the treble clef. There are good reasons for believing that the consonating note would be much higher. Now, if this explanation were true, the deeper tones of the voice, which are actually loudest in bronchophony, should be comparatively inaudible, and of acute tones one only, or one and some of its harmonics, should be conveyed to the ear. But this is certainly not the case.

*Pectoriloquy* implies the conveyance through the stethoscope placed on the chest of the articulate utterances of the person auscultated, as though he were applying his lips to the instrument and speaking through it into the ear. We have pointed out that this phenomenon is always to be heard most distinctly when the patient whispers, because it is then uninterfered with by the noise of the laryngeal notes. There is another reason why it should then be most audible. Since articulate sounds are produced in the mouth, it is obvious that, in order to reach the bronchial tubes, they must pass the portals of the larynx. But in loud speaking these portals are closed, and must hence materially obstruct the transmission of such sounds ; in whispering, on the other hand, they are to a greater or less degree patent, and the obstacle to their transmission is necessarily proportionately diminished. Pectoriloquy and bronchophony are not necessarily concurrent phenomena. Nevertheless, it is certain that pectoriloquy, like the other, is often detected both over consolidated lung-tissue and over cavities. We believe that it is most frequently and most distinctly audible over cavities which communicate freely with bronchial tubes.

*Ægophony* is a modification of bronchophony, and gradually passes into it. It is generally compared, as its name implies, to the bleating of a goat, or to the squeaking voice adopted by the exhibitors of ‘Punch and Judy.’ These comparisons are by no means inapt. The voice trans-

mitted along the stethoscope differs materially in quality from the voice as it emanates from the patient's mouth ; it is, even if musical and full-toned as uttered, tremulous, bleating, and high-pitched as it reaches the auscultator's ear. Some degree of this quality of sound may occasionally be recognised, even in health, over the lower part of the chest behind. But it is only heard in perfection in the neighbourhood of the lower angle of the scapula in cases of moderate pleuritic effusion ; and indeed, when well marked, may be regarded as pathognomonic of this condition. It is obvious that the peculiar bleating high-pitched character is due, as Dr. Stone has pointed out, to imperfect transmission of the voice, to the fact that its graver tones are lost or are greatly enfeebled in transmission, while the higher tones and the harmonics of the graver tones are comparatively unaffected. In support of this view may be mentioned the fact that the ægophonic sound, though apparently clearer, is often distinctly feebler than the normal voice-resonance to be heard over the healthy lung. Sound, as is well known, is readily transmitted through either gases, fluids, or solids, but it does not so readily pass from one of these media to the others ; and it seems obvious therefore that the sounds produced within or carried into the bronchial tubes should experience some degree of filtration (so to speak) in passing from the tubes to the solid lung-tissue, from this to fluid, from this again to the thoracic parietes, and thence through the stethoscope to the ear. High notes are more penetrating than those of graver tone, and hence would be less likely to suffer in their passage.

In association with pectoriloquy, bronchophony, or ægophony there can generally be detected a distinct whiff of tubular quality, either accompanying or following the articulate or vocal sounds. In bronchophony and ægophony this is perceptible almost exclusively at the end of syllables, and chiefly at the end of those terminating with the explosive consonants *b*, *p*, *d*, *t*, *k*, and hard *g*, and is obviously due to the non-vocal rush of air through the open glottis, which as a rule follows on the utterance of these sounds. In whispered pectoriloquy a similar whiff not only succeeds each syllable, but accompanies it during the whole period of its enunciation. These are merely tubular expiratory phenomena, due to the same cause that determines the ordinary tubular expiratory sound, and have no special significance. Under similar circumstances, a like whiff or blowing sound follows each sonorous expiratory shock of cough.

iv. *Crepitation. Râles*.—When mucus, serum, blood, or other fluids are contained in the air-tubes, the passage of air through them is attended with a variety of sounds to which the above and other names have been given. These are for the most part due to the passage of air in the form of bubbles of various sizes, and to the rupture of these bubbles at the surface of the fluid through which they pass, or to the separation of sticky surfaces. The size of the bubbles necessarily has a relation to the size of the tubes or cavities in which they occur. Thus, if they be formed in the air-cells or bronchial passages they must be excessively minute ; if in the trachea or larger bronchi they are generally

of considerable size. The sounds to which they give rise depend partly upon their size, partly upon their number, partly upon the dimensions of the channel or cavity within which they occur, and partly on the presence or absence of consolidation in the lung-tissue around. *Fine crepitation (crepitant râle)* is produced only in the air-cells and bronchial passages, and may be regarded as almost characteristic of the first stage of pneumonia. It is apparently due to the rupture of innumerable small bubbles, which individually are almost inappreciable, but collectively constitute a sound which has been aptly likened to that produced by rubbing the hair between the finger and thumb. *Crepitation (mucous râle)*.—In all forms of crepitation, except that just spoken of, the bubbles which burst at one time are comparatively few; moreover, they are individually distinguishable, and differ to some extent from one another in sound. The collective sonorous result, therefore, is more or less coarse and irregular. In some cases two or three crackles or clicks only can be detected in the course of an inspiration or expiration. In other cases they are so numerous that the whole of inspiration and perhaps the whole of expiration are noisy with them. It would be impossible to describe all the minute varieties of crepitation which may be included under the name which we have here selected. It is sufficient to say that they are probably all due to the presence of fluid in medium-sized and large tubes, that the differences which are presented depend partly on the quantity of fluid present, partly on its quality, and partly on the force with which air is driven through it, and that when the larger crepitation approaches that of pneumonia in quality, it is often termed *sub-crepitation* or *sub-crepitant mucous râle*. *Gurgling*.—This term fairly well explains itself, but is at the same time difficult to define. It implies partly large crepitation, such as may be heard in the trachea, partly the sounds which result from the mere agitation of fluid—falling, splashing, churning, and the like. It occurs in large tubes and cavities. *Metallic crepitation*.—This term may be applied to large crepitation in which the bursting of the bubbles is attended with a distinct musical twang or metallic resonance. It is developed either in cavities or in large tubes. We have pointed out that cavernous or metallic respiration is never met with in undilated bronchial tubes. The sharp, short sound, however, of a bursting bubble develops an audible resonance under conditions which would fail to affect similarly the prolonged and feeble respiratory murmur.

v. *Rhonchus*.—This word is often used synonymously with râle, and both are often applied to all varieties of unnatural sounds caused by the presence of fluid in the bronchial tubes, or by diminution of their diameter. Râle, however, strictly means rattling or crepitation, which is essentially an unmusical sound; whereas rhonchus signifies snoring, a sound always to some extent musical, and may conveniently be made to embrace all abnormal musical sounds which are occasioned in the bronchial tubes. Such sounds have sometimes a deep tone, almost exactly like an ordinary snore, or the cooing of a dove; sometimes, on the other hand, they are high-pitched and of a whistling or hissing character. The deeper notes

are usually termed *sonorous*, the acuter notes *sibilant*. The former, like the voice itself, may produce distinct fremitus in the thoracic parietes, and both may be distinctly audible, not only to the patient himself but to the bystander. The cause of rhonchus is, not the bursting of bubbles or the passage of air through fluid, but the passage of air through a tube narrowed at some point either by thickening of its parietes or by the adhesion of a plug of tenacious mucus. The almost complete closure of the tube, like the corresponding closure of the glottis in intonation, compels the passage of the air in a series of successive puffs, which soon become rhythmical, and hence a musical note results. The pitch of the musical note depends on various complex conditions, the exact influence of each one of which it would be difficult to estimate, but is determined in a very considerable degree by the size of the bronchial tube within which it is developed. Thus, as a general rule, hissing and whistling sounds or sibilant rhonchi arise in the smaller tubes, and grave tones or sonorous rhonchi are the product of the larger ones.

vi. *Splashing*.—In large cavities containing air and limpid fluid, especially therefore in cases of effusion into the pleura, associated with pneumothorax, a distinct splashing sound may often be caused by the process termed *succussion*; in other words, by giving the patient a smart shake. This sound is often audible to the patient himself as well as to other attentive listeners standing by. It may, of course, be more readily recognised by auscultation.

vii. *Amphoric bubble*.—In cases of hydro-pneumothorax may also be very rarely recognised a sound to which the name ‘amphoric bubble’ may perhaps be given. Our attention was first directed to it by Dr. T. A. Barker. On applying the stethoscope to the back in the interscapular region while the patient was sitting erect, and then making him gradually bend his trunk forwards, a sound exactly like that which occurs during the decanting of wine was distinctly audible. It was single only, but could be elicited as frequently as the patient was made to bend his body forwards to a certain angle. It was obviously due to the facts: that the partially-collapsed lung hung down from the apex of the pleural cavity so as to form an incomplete septum between its anterior and posterior parts; that the lower margin of the lung dipped into the pleural fluid, thus rendering the air-chamber behind the lung and that in front of it discontinuous; and that consequently, with change of posture, the level of the fluid tended to rise in one cavity and sink in the other, until the sudden passage of air from the one to the other was permitted under the septum.

viii. *Friction-sounds* are caused by the attrition of opposed pleural surfaces. They never occur in the healthy pleura, and it is essential for their production that the surfaces be roughened by inflammatory or other deposit. Further, as a rule, they have very little intensity, and are scarcely if at all audible beyond the spot at which they are developed. Friction-sounds present many varieties of character. In some cases there is a uniform to-and-fro murmur accompanying inspiration and expiration, and having a close resemblance to the sound produced by rubbing two

surfaces of paper together. In some cases the sound differs little if at all from some forms of intra-pulmonary crepitation: there may be a continuous crackling attending one or both respiratory movements, or merely a few isolated clicks or crepitations. In a large number of cases the sounds, whether they be fine or coarse, occur in a series of irregular jerks. The jerks, indeed, may exist without the presence of actual friction-sounds, in which circumstances the respirations become (over limited *aréæ*) 'jerky,' or, as they are commonly called, 'wavy.' Friction-sounds have received various names, such as grazing, rubbing, creaking, and the like, which to some extent express their quality. They have also been described as 'superficial' in character. It need scarcely be remarked, however, that this epithet can have no other meaning, as applied to sounds, than that they are loud or distinct. Its use is altogether objectionable, as tending to cause confusion between the facts which we observe and the inferences we deduce from them. In cases of pleural friction, the rubbing of the opposed surfaces may produce a tremor in the thoracic walls, readily detectable by the hand. It may be observed that loudness or roughness of friction-sound by no means necessarily implies either roughness, hardness, or abundance of lymph. The loudest and coarsest sounds are occasionally produced by the thinnest, softest, and most recent films.

#### E. *Detection of Cavities, Consolidated Lung, and Pleural Effusion.*

Before leaving the subjects of auscultation and percussion it may be convenient to recapitulate the phenomena which attend and indicate the presence of cavities, consolidated lung, and pleural effusion.

1. *The detection of cavities* is often very important; and in a large number of cases, no doubt, by considering the patient's history, the results of periodical examinations of his chest, and the presence or absence of certain special acoustic phenomena, we may arrive at a fairly correct conclusion. But the acoustic phenomena which by their presence prove the existence of a cavity are, as Skoda asserts, very few indeed. Dulness, *bruit de pot fêlé*, normal resonance, tympanitic resonance, high-pitched resonance may each be present. Feebleness, with indeterminate character of the respiratory sounds, tubular sounds, gurgling, may also each be present in its turn. There is probably always more or less marked bronchophony and pectoriloquy. Pectoriloquy, indeed, is more distinct, as a rule, over cavities than over merely consolidated lung. The only sounds, however, which positively indicate the presence of a cavity, are: first, the musical or metallic ring or resonance which sometimes accompanies the respiratory sounds, the voice, the movements of fluid in the cavity, and the percussion stroke upon its walls; second, the splashing sound caused by succussion; and, third, the production of the amphoric bubble to which we have adverted. But these sounds may all be absent from cavities even of large size.

2. *The conditions which collectively indicate consolidation* are sense of resistance, impaired or annulled resonance, increase of vocal fremitus, tubular breathing, or correspondingly modified conditions of rhonchus or

crepitation, bronchophony, and pectoriloquy. These conditions are, however, by no means necessarily all present in every case.

3. The *indications of pleural effusion* are dulness on percussion, with variation of the limits of dulness and resonance in accordance with variation of posture, tubular breathing, or more frequently extreme feebleness or absence of respiratory sound, impairment or suppression of vocal fremitus, and ægophony. To which may be added, dilatation of the affected side and intercostal spaces, with sometimes obvious fluctuation, and displacement of the diaphragm downwards, and of the mediastinum to the opposite side. But, again, many of these phenomena are often absent from otherwise well-marked cases of effusion.

---

## II. LARYNGITIS AND TRACHEITIS

*Causation.*—Laryngeal and tracheal inflammation is caused mainly by exposure to cold or wet, or both. It is then sometimes the primary affection, but is often a mere extension of ordinary catarrh or of acute bronchitis. It may be due, however, to many other causes: to the local operation of irritating gases, fluids, or solid particles, among which may be enumerated boiling water, vomited matters, and puriform secretions furnished by the lung itself; to the presence of certain morbid conditions or diseases, such as variola, measles, scarlet fever, diphtheria, erysipelas, syphilis, and tuberculosis; to the extension of inflammation from subjacent tissues; and even, as regards the larynx, to sustained or violent exertion, as occurs in clergymen and other public speakers, and in those who strain themselves in coughing or shouting. It may be determined also by local violence. There are, further, many conditions which predispose to it; among the most important of which is the fact of having suffered from a previous attack, or the presence of Bright's disease.

*Morbid anatomy.*—The local changes which attend and indicate laryngitis are those of inflammation of mucous membrane generally, with modifications due to peculiarities of arrangement and structure which the laryngeal tissues present. The mucous membrane and subjacent parts are congested and œdematous; and the epithelial surface, at first (as in ordinary nasal catarrh) preternaturally dry, soon secretes, though not in large quantities, a glairy, transparent mucus, which subsequently becomes thick and muco-purulent. In ordinary mild cases the tumefaction and reddening are slight yet pretty uniformly diffused—the vocal cords probably being injected and swollen, and studded with flakes of adherent mucus. In more severe cases the submucous tissue may be largely infiltrated and œdematous; and hence the affected regions become much swollen, deeply congested, in parts translucent or almost jelly-like in aspect, and may be the seat of interstitial suppuration. Such swelling, or œdema, may affect mainly the epiglottis, aryteno-epiglottidean folds, false vocal cords, or some other limited tract, or may be general. It must be borne in mind, however, that the parts whose tissues are closest in

texture suffer least in this respect, and that hence the free edge of the epiglottis and the true cords for the most part escape. In the severer cases just referred to the inflammation is apt to involve the pharynx, or upper part of the œsophagus, or the deeper tissues of the neck, the larynx being either primarily or secondarily affected. In most cases the secretion from the mucous membrane presents simply the ordinary characters of mucus or muco-pus. But in some (even in the absence of diphtheria) an adherent false membrane forms upon the surface. This sometimes follows the attempt to swallow boiling water.

Ulceration is an unusual sequel of ordinary inflammation. It occurs most commonly, perhaps, in the course of phthisis and constitutional syphilis, even when no specific lesions are present. Ulceration in phthisis may possibly be the result of simple excoriation, but is usually if not always due to the breaking down of miliary tubercles. It begins with the formation of round or oval shallow, saucer-like depressions, of an ashy colour and with congested margins. Its most important, if not commonest, seat is the point of the processus vocalis. Ulcers in this situation incline to extend deeply, to expose more or less of the arytenoid cartilages, and to lead to their partial or total destruction by caries or necrosis. There is a great tendency, indeed, both in phthisis and in syphilis, for ulceration to involve the cartilages (arytenoid, cricoid, and thyroid), and to cause their erosion or necrosial destruction. But in some cases the cartilaginous affection takes its origin in inflammation of the perichondrium. For the most part the necrosed cartilages have undergone more or less complete ossification. The forms of laryngitis last referred to may be regarded as essentially of a chronic nature; but simple laryngitis also may become chronic. The anatomical characters of this variety differ but little from those of the acute affection. The chief distinctions are that, in the former case, the inflammatory redness is less intense, and the thickened tissues are more opaque and apparently more solid, thus losing their peculiar œdematous character. When laryngitis becomes chronic the follicles of the affected surface often undergo hypertrophy. To such cases the name of *glandular laryngitis* has been given.

The changes which take place in tracheitis are essentially identical with those which characterise laryngitis. The surface, which is at first drier than natural, soon secretes an over-abundance of modified mucus, and occasionally, like that of the larynx, gets covered with an adherent pellicle. The mucous membrane itself, and the subjacent tissues, become congested and infiltrated, and not unfrequently, especially in syphilis and phthisis, ulceration takes place. The ulcers are mostly, in the first instance, mere excoriations, which tend gradually to increase in area and thus to coalesce, and in depth so as gradually to expose the cartilages. The latter may thus get eroded or necrosed, and even detached and expectorated. Abscesses may form in the walls of the trachea or external to them, and communications may be established between its tube and that of the œsophagus. The healing of ulcers, whether in the larynx or trachea, may produce serious cicatricial contraction.

*Symptoms and progress.*—1. *Acute laryngitis* is dangerous mainly from the fact that it is liable to cause serious obstruction to the passage of air through the rima glottidis, and hence death from suffocation. The inflammation is for the most part of little intensity, and gives rise to comparatively slight constitutional disturbance. There is usually during the earlier period of the affection elevation of temperature, acceleration and hardness of pulse, flushing of the face, furring of the tongue, thirst, and loss of appetite. But in favourable cases these symptoms soon subside, and in unfavourable cases get replaced by those of asphyxia.

The special symptoms of laryngitis are often preceded by those of ordinary catarrh, and especially by those of catarrhal affection of the fauces, which, in many respects, they resemble. The patient complains of dryness or roughness, soreness, itching, pricking, or aching, or it may be of several or all of these sensations, which he refers to the back of the throat and to the region of the thyroid cartilage. There is generally also some tenderness to touch, and there may be absolute pain when the parts are roughly handled. The sense of soreness is aggravated by the act of swallowing, especially if solid matters be taken, and there is commonly also a good deal of aching thus caused besides soreness. The dryness and irritability of the throat compel the patient nevertheless to make constant efforts at deglutition, and at clearing the throat, and excite more or less frequent spasmodic attacks of cough. The voice gets altered in quality, and respiration somewhat impeded. Examination with the laryngoscope reveals congestion and thickening of the mucous membrane; and if the parts above the vocal cords be much affected they may entirely conceal the rima glottidis and its surroundings from view.

Certain of the symptoms here enumerated require to be considered a little more in detail. Some degree of interference with the freedom of respiration is probably always experienced, and this, under the influence of excitement or sudden spasm, may readily amount to manifest dyspnoea; expiration is a little prolonged, and tends perhaps to be wheezy. But very often matters become much more serious; both inspiration and expiration (the former more especially), even when the patient is at rest, get harsh or whistling, noisy and prolonged, and he suffers from continuous difficulty of breathing. In cases of still greater severity all the symptoms of asphyxia become developed: the patient sits up in bed gasping for breath, which is still harsh, wheezy, or whistling; with his head thrown back, his mouth open, his nostrils dilated, his respiratory muscles acting with spasmodic force; anxious, restless, throwing his arms about, or clutching at any support which may be near; with eyes prominent and staring, face livid and ghastly, skin bathed in sweat, and pulse rapid, small, failing, and perhaps irregular. Under these circumstances death may occur suddenly from complete obstruction of the rima glottidis. But more commonly the patient begins to ramble, and presently passes into a condition of insensibility upon which death gradually supervenes.

The voice is almost invariably altered in quality; it becomes hoarse, uncertain, or reduced to a whisper. In the beginning it is in general

merely hoarse; it is somewhat rougher than natural, and at the same time deeper toned—phenomena which depend either on the adhesion of mucus to the edges of the vocal cords, or on some modification in their thickness, elasticity, or tension. This hoarseness is sometimes apparent only on rising in the morning, and disappears during the day; it is apt, however, to be brought on again, and to be converted into actual aphonia, by unwonted use of the voice. At a later period of the disease, when the tissues above the vocal cords are highly œdematous, or the cords are much thickened and scarcely movable, complete aphonia is usually present.

The cough varies in severity; sometimes it is incessant, or comes on in uncontrollable paroxysms. But it is generally attended with so much pain in the larynx that the patient endeavours (probably in vain) to suppress it. It is always at first, like the voice, hoarse and loud; and in many cases, especially in children, and where there is manifest dyspnœa, its inspiratory element is long, loud and whistling, and the expiratory effort is attended with a remarkably harsh, sonorous, metallic clang. Later on, the cough, like the voice, becomes ineffectual, wheezy, or aphonic.

Acute laryngitis is very apt to be attended or followed by bronchitis, or, especially in children, by collapse and lobular pneumonia—complications which aggravate the patient's symptoms and add materially to his danger. It is sometimes as rapidly fatal as almost any disease with which we are acquainted, but in a large proportion of cases is so mild in its symptoms that but little attention is paid to it; yet it is always attended with risk, and should be carefully treated.

The frequency of the occurrence of laryngitis in a mild form is evidenced by the frequency with which persons, after exposure to cold, suffer from soreness referrible to the larynx, and hoarseness or loss of voice. This affection generally lasts for three or four days, subsides with increase of laryngeal secretion, and leaves no ill-consequences behind. Dr. Cheyne asserts that hoarseness is an uncommon phenomenon in the catarrhal affections of young children, and that its occurrence should make us dread the supervention of croup. Our own belief, on the other hand, is that hoarseness is not uncommon in children, and that it has no more serious import in them than in adults. The phenomena, however, of slight laryngitis in children under two or three years of age, and even in those who are a little older, are often so remarkable that they are confounded with those of *spasmodic croup* or *laryngismus stridulus*. The child, after having suffered from slight catarrhal symptoms, or sometimes in the midst of apparently good health, wakes suddenly during the night in an agony of dyspnœa. He starts up in bed with a look of extreme anxiety and terror, gasps for breath, inspires laboriously with a hissing or whistling sound, and coughs at intervals with a series of harsh, loud, metallic, expiratory shocks; his voice is hoarse or reduced to a whisper. After the symptoms have lasted half-an-hour or more, during which time the patient has been enduring all the horrors of impending suffocation, they subside, the skin gets moist, and he falls into a comfortable sleep.

The next day he probably appears to be pretty well, although there may still be some hoarseness of voice, and the cough may still have a croupy character. It is not uncommon for such attacks to occur two or three nights or more in succession. There can be no doubt that they are mainly spasmodic; and there is some reason to suspect that they are often induced immediately by the entrance of saliva, or even of regurgitated food, during sleep, into the larynx. They are seldom fatal. Neither of the above forms of laryngitis, however, differs essentially from the rarer cases in which the symptoms early assume an aggravated character, and in which the patients die, suffocated, after periods varying from a few hours to two, three, or four days.

The phlegmonous form of laryngitis, or that in which the inflammation is of an erysipelatous character, and involves the deeper tissues, is attended for the most part with high fever and serious constitutional disturbance; there is generally great pain and difficulty in swallowing, sometimes absolute inability to swallow, and the laryngeal symptoms tend speedily to assume an aggravated character. Such cases are apt to take a rapidly fatal course.

2. *Chronic laryngitis*.—Under the head of chronic laryngitis may be included: first, simple laryngitis, which has assumed a chronic form; second, aphonia clericorum; and third, ulcerative processes, connected especially with pulmonary tuberculosis and syphilis.

In the first variety the symptoms differ but little from those of the acute affection, excepting in their comparative mildness. They are liable, however, to exacerbations, and rapid œdema of the submucous tissue may at any time ensue. Sir M. Mackenzie states that in this form of chronic laryngitis the aryteno-epiglottidean folds are comparatively rarely congested and swollen, but that it is chiefly the false vocal cords, capitula Santorini, and epiglottis that suffer.

Aphonia clericorum may originate in catarrh, like other forms of laryngitis, or may be the result of simple over-exertion. It soon, however, and mainly in consequence of the persistent use of the voice, becomes a chronic affection. Its symptoms are like those of ordinary chronic laryngitis, but on the whole are more mild. The patient, indeed, often suffers from little except a sense of dryness in the throat, persistent hoarseness, and a tendency to hawk and clear the throat. Laryngoscopically, the appearances are those of chronic laryngitis. It is stated, however, that in this case there is a special tendency to hypertrophy of the laryngeal glands, and that their enlarged orifices may often be distinctly recognised.

The laryngeal affection which so commonly attends pulmonary phthisis creeps on insidiously, and is sometimes far advanced before the pulmonary disease has made very manifest progress. It differs from the varieties of chronic laryngitis above considered in its progressive aggravation and its incurability. At the beginning it presents no special symptoms; but, as the disease goes on, complete aphonia, dyspnoea which may be exceedingly severe, and pain and difficulty in swallowing become established; indeed, in many cases swallowing becomes almost impossible, on account of the

passage of food through the rima glottidis when the act is attempted. On laryngoscopic examination, the soft parts are seen to be more or less thickened, sometimes congested, sometimes pale, and for the most part opaque; and Morell Mackenzie draws attention to the fact that the aryteno-epiglottidean folds usually look like 'two large, solid, pale, pyriform tumours, the large ends being against each other in the middle line, and the small ones directed upwards and outwards.' The presence of ulcers may sometimes be recognised. The symptoms to which syphilitic affections of the larynx give rise are those of progressive chronic laryngitis. In the later stages of constitutional syphilis extensive ulceration of the larynx is not uncommon, and in this case, as well as in so-called 'laryngeal phthisis,' there is a great tendency for caries or necrosis of the various cartilages to take place. Here, however, the epiglottis is most prone to suffer. Such complications, no matter what their cause, always largely diminish the ultimate prospect of even partial recovery, and bring in their train special symptoms, in addition to those of simple laryngitis. Among these may be mentioned: infiltration and œdema of the tissues of the neck superficial to the laryngeal cartilages; fetid breath and purulent discharge; the occasional separation of portions of cartilage or bone, which may either be expectorated or cause sudden death by obstructing the laryngeal orifice; the formation of abscesses or sinuses which may open in various positions; the perforation of arteries, with profuse and fatal hemorrhage; and occasionally, as a sequela of the separation of sequestra and cicatrisation, permanent and serious contraction of the glottis or other parts of the laryngeal canal.

3. The symptoms due to tracheitis are scarcely distinguishable from those of inflammation of the larynx. It may be observed, however, that in inflammation limited to the trachea there is not necessarily any pain in the pharyngeal stage of deglutition, or any affection of the musical quality of the voice, and that, while the danger of suffocation is less, the benefit to be expected from tracheotomy is also less. Further, some tenderness in the course of the trachea may be expected, some pain in the same situation on coughing, and some tenderness or soreness in the passage of food along the œsophagus.

*Treatment.*—The treatment of laryngitis may be divided into the constitutional or general, and the local, of which the latter is by far the most important. The local treatment to the exterior of the larynx comprises leeches (which should be applied over the upper part of the sternum), blisters and other counter-irritants (which are also best applied in the same region), and poultices or hot fomentations over the larynx itself. For internal local treatment may be employed: the inhalation of steam, simple, or medicated with volatile aromatic or sedative substances such as turpentine, camphor, benzoin, creasote, or conium; the inhalation of atomised fluids such as solutions of sulphate of zinc or copper, acetate of lead, alum, nitrate of silver, perchloride of iron, or tannin; the application, by means of a sponge or brush, of strong solution of nitrate of silver (5j ad 3j), tincture of perchloride of iron (5j, 5ij, ad 3j), or any of the

other articles just enumerated; the insufflation of finely-powdered astringents or sedatives; and scarification of the congested or œdematous tissues. In order that the internal local treatment may be effectual, it is important that (excepting in the case of simple inhalation) the remedies should be applied by means of special apparatus under the guidance of the laryngoscope. The application of ice or cold compresses to the exterior of the larynx, and the sucking of ice, are measures which may often be adopted with advantage. As to general treatment, we must be governed mainly by the constitutional condition of the patient and by the character of his attack. In acute cases, ipecacuanha, tartar emetic, and other nauseating remedies have been largely advocated; opium, as in most inflammatory affections, especially such as are attended with pain or distress, is often of extreme value. Warm baths, and the retention of the patient in an equable, warm, moist atmosphere, are generally of use in the treatment of acute cases; in the treatment of chronic cases, iron and other tonics, cod-liver oil, change of air, and, if need be, iodide of potassium, or mercurial salts.

In the laryngitis which so often attends an ordinary catarrh it is advisable to keep the patient in a warm atmosphere, at any rate free from exposure to draughts, to apply hot fomentations or mustard plaisters externally, to order him to gargle his throat frequently with warm milk or with slightly astringent solutions, or to relieve his faucial discomfort by the use of gelatinous or oleaginous substances (among which may be included common calves'-foot jelly and black-currant jelly), or to inhale steam. Diaphoresis may be encouraged, and expectorant medicines may be administered. Opium is of great value in relieving the patient's discomfort. When the case is severe from the beginning, or when it begins to assume a serious aspect, our local treatment must be more active; leeching externally, and scarification within, become then of great importance. Sometimes in such cases swabbing the throat with strong solution of nitrate of silver, perchloride of iron, or alum, is followed by the best results. In the stridulous laryngitis of young children the danger is mainly momentary (so to speak), and due to spasm; and treatment, therefore, if it is to be efficacious, must be prompt. Generally it is advisable to place the patient in a hot bath, and to apply a sponge wrung out of hot water over the larynx. It is usually customary to administer an emetic dose of ipecacuanha or sulphate of zinc. It may, however, be questioned whether the inhalation of chloroform is not more likely to be beneficial than the use of an emetic. In the chronic form of laryngitis local bleeding and scarification are rarely necessary except to relieve exacerbations; but blisters and other counter-irritants externally, and the systematic employment of medicated applications to the interior of the larynx, are then specially indicated. In the so-called 'aphonia clericorum,' prolonged rest from the use of the voice should especially be enjoined. In all cases, whether they be acute or chronic, specific or non-specific, it must be borne in mind that we may be called upon at any moment to save life by the performance of tracheotomy. The need for its perform-

ance must generally be determined at the moment. It is difficult to lay down precise rules for the guidance of the judgment of the medical attendant in such cases. It is probably sufficient to say that no one ought to be permitted to die of uncomplicated laryngeal obstruction without having that chance of recovery given him which tracheotomy affords; that it is unwise to delay the operation until the patient is moribund; that it is better to perform it needlessly than too late; and, lastly, that it should not necessarily be discarded even if the patient appears to be just dead.

---

### III. BRONCHITIS.

*Causation.*—Inflammation of the bronchial tubes is dependent chiefly on exposure to cold. But it also arises, like laryngitis, from the inhalation of irritant matters; as a complication or sequela of various febrile disorders, such as influenza, whooping cough, measles, and typhoid fever; and in connection with various idiopathic affections, more especially heart and kidney diseases. It may also be developed under the influence of pulmonary tuberculosis and carcinoma, and probably, too, in connection with syphilis and gout. Its prevalence depends largely upon temperature and season, and hence it is chiefly fatal in autumn and winter; it is favoured by such occupations as expose persons to the influence of irritant or other noxious matters, and such as necessitate frequent and sudden exposure to variations of temperature; it affects persons of all ages and of either sex, but it has a marked preference for such as have had previous attacks, and is especially fatal in early infancy and in old age.

*Morbid anatomy.*—Inflammation of the bronchial tubes, like inflammation affecting other mucous membranes, is attended with changes in their epithelial covering and glandular secretions, and in the subjacent tissues.

The discharge is, in the first instance, diminished in quantity, but soon becomes more abundant than in health, thin, transparent, and either watery or viscid, and subsequently acquires more or less opacity and thickness, and a yellowish or greenish tint. Sometimes it remains watery, sometimes assumes the characters of pus and not unfrequently, if the inflammation be intense or the congestion great, presents streaks and spots of blood. Under the microscope the viscid transparent secretion presents abundance of shed ciliated epithelial and other cells; and the acquisition of opacity is connected with the replacement of these by cells of embryonic character, fatty or granule cells, and pus corpuscles. In some rare cases groups of bronchial tubes are found occupied by laminated fibrinous casts, which on separation present a branching or tree-like aspect.

The mucous membrane becomes congested, sometimes intensely congested, and the seat of minute extravasations of blood; at the same time it undergoes infiltration and thickening, and may even acquire a granular or villous aspect, and a soft or pulpy consistence. It is important, however, to know that, in a large number of cases, especially chronic cases,

the congestion disappears wholly after death, and the mucous membrane seems scarcely changed either in thickness or in texture.

The inflammatory process may be limited to the surface of the mucous membrane; but it often pervades the submucous tissue; and in some cases involves the whole thickness of the bronchial walls, leading also to infiltration and induration of the connective tissue which surrounds them. In the last case the muscular fibres may either, if merely irritated, be stimulated to unwonted action, or undergo atrophy or degeneration, and lose their contractile properties. In most cases of bronchitis the mucous membrane remains whole; but occasionally ulceration takes place. This is more common in phthisis than in the uncomplicated disease. The ulcers, at first small and round or oval, gradually enlarge and coalesce, and at the same time tend to increase in depth. Thus the walls may undergo gradual removal (the cartilages disappearing by caries or necrosis), the surrounding lung-tissue share to a greater or less extent in the destructive processes, and the tubes be converted into irregular channels bounded by diseased lung-tissue. In some cases gangrene occurs. Ulcerative destruction occasionally takes place from without, as when a pulmonary, glandular, or other abscess opens into an adjoining tube. It is thus that abscesses about the roots of the lungs discharge themselves into the bronchi, and that calcareous matter from diseased bronchial glands finds its way into these or smaller tubes.

Bronchitis is limited, in a large proportion of cases, to the tubes of large and medium size; but sometimes affects mainly or entirely the minuter tubes. In the latter case, not only is the affection marked by greater intensity of symptoms and aggravated danger to life, but the local pathological changes assume a more serious character; the thickening of the mucous membrane encroaches more seriously on the channels of the affected tubes, and their secretions tend to accumulate in them and to block them up completely. Hence post mortem we not unfrequently find the smaller tubes distended with pus or mucus, void of air, and quite impermeable.

The indirect influence of bronchitis over the structural condition of the bronchial tubes and proper tissues of the lungs is very remarkable. As regards the tubes, we have already pointed out that, by extension of ulceration, they may be converted into irregular channels; this change may be seen in its greatest perfection in connection with the capillary or terminal tubules. But independently of ulceration, the tubes, and especially the smaller ones, may undergo considerable dilatation from the combined effects of simple accumulation of contents and inflammatory weakening of their walls. In acute bronchitis, attended with much secretion, the lung-tissue often becomes preternaturally distended with air, and retains the accumulated air even after death; this condition is sometimes incorrectly termed emphysema; but it not unfrequently proceeds to actual emphysema, in which the vesicular structure is more or less seriously disorganised. Besides over-distension, the exactly opposite condition of pulmonary collapse is often met with, sometimes alone, sometimes associated with

over-distension of other parts. Collapse is intimately related to another frequent complication of bronchitis, and indeed passes by insensible gradations into it; we mean lobular pneumonia. All the secondary phenomena arising in the progress of bronchitis, which have here been enumerated (namely, dilatation and destruction of tubes, dilatation and destruction of air-cells or emphysema, lobular collapse and lobular pneumonia), form a more or less important part of chronic bronchitis, and tend both to aggravate its symptoms and to perpetuate them. It will, nevertheless, be convenient to defer their complete discussion.

*Symptoms and progress.*—The symptoms of bronchitis comprise, in varying proportions, those of inflammatory fever, those of defective aëration of blood, and those directly referrible to the condition of the bronchial tubes and lungs; to which may be added those arising from mechanical impediment to the transmission of blood through these organs.

The symptoms of inflammatory fever are always most pronounced at the commencement of acute attacks and of exacerbations of the chronic affection, and often disappear wholly, to be replaced by other conditions, during the progress of the disease. The temperature, excepting in very severe cases, especially of capillary bronchitis, and in young children, usually does not exceed  $100^{\circ}$  or  $101^{\circ}$ . It may, however, mount to  $102^{\circ}$ ,  $103^{\circ}$ , or  $104^{\circ}$ . With elevation of temperature there may at first be chills or rigors, and dryness of skin. But perspirations, more or less profuse, are apt to alternate with dryness, or to replace it. The pulse becomes accelerated, the respirations hurried, the tongue furred; the patient has thirst, loss of appetite, constipation, and scanty turbid urine; he probably complains of headache and febrile pains in his limbs; and he is apt to be drowsy, though often wakeful at night.

Diminished aëration of the blood tends to the reduction of temperature, to interference with the processes of nutrition, and to enfeeblement of the heart's action and of the pulse. The temperature of bronchitis may hence be subnormal even in acute attacks. The pulse, moreover, is sometimes full and incompressible, owing either to increase of arterial tension secondary to venous obstruction, or to poisoning of the nervous centres; and in chronic cases it is often abnormally slow. The face, and especially the lips and cheeks, assume a pale or livid hue; profuse perspirations break out; and there is a tendency to impairment of the mental faculties, to delirium, and coma.

The local symptoms are due to the processes going on in the bronchial tubes. They comprise cough, at first dry and irritable, later on freer and attended with expectoration; difficulty of breathing, with increase in the number of respirations and in the efforts required of the patient; comparative prolongation of the acts of expiration; and the various forms of rhonchus and crepitation, which are caused by thickening of the bronchial mucous membrane, or secretion into the tubes.

1. *Acute bronchitis.*—The symptoms of bronchitis vary considerably according to its severity and the conditions which cause or complicate it. In its mildest form it is a comparatively trivial affection. It then usually

commences with ordinary catarrhal inflammation of the upper part of the respiratory tract, which gradually travels downwards, involving first the larynx, and then the bronchial tubes. It is attended with febrile disturbance, irritability of the bronchial mucous membrane, tickling or uneasy sensations in the throat, burning, soreness or rawness within the chest, and cough, the paroxysms of which cause considerable aggravation of the intrathoracic discomfort. There is frequently, also, tenderness over the manubrium, with tenderness and aching of the muscles of the upper part of the front of the chest. The cough is at first dry, but in a short time becomes loose and attended with the discharge of transparent glairy mucus. With the progress of the case the sputa get opaque and mucopurulent, then gradually cease, and health is restored at the end of a few days, or at most after the lapse of a week or two.

In more severe cases, the symptoms are the same in kind, but aggravated. The febrile phenomena which usher in the attack are more intense, the cough and pain in the chest are more distressing, and there is more or less obvious dyspnoea. There may, indeed, while the mucous membrane is simply swollen, and the cough is yet dry, be great asphyxial distress and lividity of surface, and the patient may even at this stage die asphyxiated. More commonly, however, here as in the former case, the mucous surface ere long begins to discharge, and the cough to be attended with expectoration, which, except that it is probably much more profuse, and apt to be streaked with blood, passes through the ordinary phases. During this period, also, death may take place from accumulation of fluid in the bronchial tubes and consequent slow asphyxia; or, without the actual supervention of asphyxia, the patient may gradually pass into a typhoid state, with feeble, quick, irregular pulse, dry cough, copious sweats and delirium; or he may sink from a combination of these conditions. Occasionally death is sudden owing to the sudden obstruction of some of the larger tubes.

The most dangerous form of acute bronchitis is that which commonly goes by the name of *capillary bronchitis*. It is that form in which the inflammation affects mainly, if not exclusively, the minuter bronchial tubes. It is most common in children, yet is not unfrequent in persons of more advanced age. The fever which ushers it in is generally pretty intense, the difficulty of breathing and lividity are considerable; the cough, however, may be much less troublesome than in other cases, and even during the stage of secretion may, owing to the difficulty of dislodging accumulations in the minuter tubes, remain inefficacious and dry. Further, there is generally comparatively little intrathoracic pain even in violent coughing. The tendency in capillary bronchitis is to speedy death from asphyxia and debility.

The auscultatory phenomena of bronchitis comprise mainly sonorous and sibilant rhonchi, and crepitation of various sizes. Musical rhonchi are chiefly heard during the dry stage, crepitation during the later stages, but even then musical sounds are apt to be present to a greater or less extent. In capillary bronchitis the rhonchus is mostly sibilant, and the crepitation

small. The sounds elicited by percussion differ little from those of health. If the lung-tissue be much distended with air, as it often is, the percussion sound may be somewhat more resonant than normal ; but obvious dulness is rarely produced, even if there be lobular collapse, unless the collapse be extensive, or pneumonia or other complications be present.

2. *Chronic bronchitis*.—Bronchitis often assumes a chronic form, especially among the labouring classes, and in middle or advanced life. It may become chronic, however, at all ages, and in persons of any grade of society. When a patient suffering from acute bronchitis continues to expose himself to the conditions which caused it, the inflammation is likely to be kept up ; and, again, bronchitis is one of those affections which, when once they have been experienced and cured, tend to recur on the slightest provocation. The ordinary history of a case of chronic bronchitis is to the effect that the patient, after exposure to weather, probably during the winter, has an attack of the disease, from which he recovers during the ensuing spring, remaining fairly well until the approach of the following winter ; that then a fresh attack is contracted, from which again recovery takes place ; that these attacks of winter cough then recur annually, gradually increasing in severity and duration, and being separated from one another by shorter and shorter intervals of comparatively good health ; and that each such successive interval becomes a period of increasing shortness of breath, until it merges in that of the bronchitic condition, which thus becomes continuous, although still probably presenting winter exacerbations. Each bronchitic attack differs but little in its symptoms from an ordinary acute seizure, excepting perhaps that it is rarely attended with such manifest febrile disturbance, and that the expectoration is apt speedily to assume the muco-purulent condition and to continue of this character, and at the same time to become more or less abundant, until the approach of the long-delayed convalescence.

These successive long-continued attacks generally lead gradually but surely to those structural pulmonary changes which have been already enumerated, and to those various remote lesions referrible to long-continued congestion of the systemic venous system which follow equally on this disease and on cardiac affections ; the mucous membrane tends to secrete more abundantly than natural, even when the patient is otherwise apparently well ; emphysema, or dilatation of the tubes, or both of these conditions, gradually supervene ; the right side of the heart becomes dilated and hypertrophied ; and systemic venous congestion ensues, in which the liver and kidneys especially share. The symptoms due to these lesions are consequently added one after another to those of simple bronchitis ; the patient soon begins to suffer from persistent shortness of breath and bronchial accumulation, and sooner or later gets cyanotic, anasarcaous, and the subject, maybe, of jaundice, albuminuria, or both.

The thorax of a patient who has suffered long from chronic bronchitis gradually assumes, in consequence partly of his persistent powerful inspiratory efforts, partly of emphysema, a rounded form—the well-known barrel shape so common in this affection.

Cases of chronic bronchitis, within certain limits, differ widely from one another in their severity and in the symptoms with which they are attended. In some the bronchial secretion is so scanty, other symptoms being well-developed, that the affection has been termed *dry bronchitis*; in some the discharge is so profuse that the name *bronchorrhœa* has been given to the malady; and, in other cases, even where no gangrenous condition is present, the expectoration is disgustingly fetid—a condition said to be chiefly met with when there is dilatation of the bronchial tubes. The expectoration and the auscultatory, percussive, and tactile phenomena yielded by persons suffering from chronic bronchitis do not differ materially from those presented by patients suffering from the acute disorder, and call, therefore, for no special description. Death, in which, sooner or later, the chronic disease so often terminates, is usually due to asphyxia, asthenia, or a combination of these conditions.

The expectoration of laminated casts of the bronchial tubes is an event which may naturally be looked for in cases of diphtheria in which the diphtheritic process has travelled from the larynx into the trachea and thence downwards. And, indeed, since the diphtheritic pellicle may form upon any part of any mucous membrane, there is little doubt that it occasionally forms in the smaller bronchial tubes independently of any such affection of the larynx, trachea, or bronchi, and that equally under these circumstances expectoration of casts may take place. But occasionally such casts are spat up from time to time by patients, whom there is no reason to suspect of diphtheria. The causes, pathology, and symptoms of this affection, which has been termed *plastic bronchitis*, are alike obscure. All that is positively known is: that persons, after a longer or shorter period of ill-health, and symptoms something like those of slight chronic bronchitis or lobular pneumonia, expectorate either without warning or after prolonged dyspnœa, and as the result of a suffocative paroxysm of cough, a larger or smaller quantity of this material, often in connection with hæmoptysis, which may be profuse, or with muco-purulent discharge; that this plastic expectoration may then cease, or may continue off and on for an indefinite period; and that, although some of these patients die ultimately of phthisis, or of the accidents which attend the process of expectoration, the majority appear to make a good and permanent recovery. There is good reason to believe that the portions of lung-tissue to which the obstructed tubes lead are in a state of collapse or lobular pneumonia; and, indeed, although in most cases there appears to have been perfect pulmonary resonance with more or less rhonchus and crepitation, a few have been recorded in which, as might be expected, there was circumscribed dulness, with total absence of respiratory murmur over the dull area. The co-existence, however, of pulmonary and bronchial lesions does not explain the nature of the relation between them. There is no doubt that, in hæmoptysis, blood occasionally coagulates in the bronchial tubes, and that in pneumonia bronchial casts of the same material that fills up the air-cells are now

and then produced ; but these seem to be distinct from the casts of plastic bronchitis, which probably originate *in situ*.

*Treatment*.—Bronchitis is one of the commonest diseases of temperate climates, one of the most frequent sources of incapacity for useful work and the enjoyment of life, and one of the most fruitful causes of death. Its treatment is therefore a matter of grave importance. It will be convenient to discuss it under different heads. *Hygienic treatment*.—This comprises the keeping of the patient in an equable and moderate temperature, not below 65° or 66°, and if possible not very largely exceeding this, and preferably, therefore, confining him to the house or even to one room ; the maintenance of some degree of moisture of atmosphere ; the use of hot baths, the Turkish bath, or the hot pediluvium ; and the regulation of the diet according to the patient's capabilities and needs. *Local treatment*.—Under this head may be included : first, treatment applied to the skin, inclusive of counter-irritation by mustard plaisters, blisters and the like, dry-cupping, and the abstraction of blood by leeches or cupping-glasses ; second, treatment applied to the mucous membrane, such as the inhalation of steam, either simple or medicated with some of those substances which have been enumerated in the treatment of laryngitis. *Medicinal treatment*.—The drugs which have been employed are various. Among expectorant or nauseating medicines, ipecacuanha, squills, and tartar emetic hold a high place ; stimulant drugs, such as the gum-resins and balsams, more particularly benzoin, tolu, guaiacum, and ammoniacum, are often valuable ; and as closely related in action to these may be enumerated ammonia, senega, and the stimulant vegetable tonics. Sedatives and narcotics, such as opium, conium, belladonna, and hyoscyamus, are of great importance ; and in certain stages and in certain cases so also are sulphuric ether and lobelia. Lastly, tonics and alcoholic stimulants are often, and especially in the later stages of the acute affection and in chronic cases, of extreme value.

In ordinary mild bronchitis, little or nothing is needed beyond keeping the patient in a warm room, the inhalation of steam, the application to the chest of a mustard plaister, the use of the hot bath or pediluvium, the exhibition of small quantities of opium and ipecacuanha, and the relief of thirst and dryness of mouth by warm diluent drinks.

In acute cases of greater severity, it may be necessary to abstract blood from the surface of the chest. This can only be needed when there is extreme difficulty and pain in breathing, especially if at the same time there is reason to believe that the bronchial membrane is congested and swollen, and yielding but little secretion. The quantity of blood to be removed must be determined by the age and state of the patient, and by the effect of its removal. It is much better, however, to withdraw an adequate quantity at first than to repeat the operation over and over again. In such cases, too, counter-irritants and inhalation are of great value. As regards medicines, antimony or ipecacuanha in nauseating doses, combined, it may be, with squills, and above all with small doses of opium, and frequently administered, is generally useful. When the

bronchial secretion becomes abundant and muco-purulent, these may still be continued, or may be replaced by the more stimulating forms of expectorant medicines. In this stage the combination of drugs recommended by Dr. Stokes, namely, ammonia, opium, and senega, is often of much service, as also are the balsams or gum-resins. When the patient suffers much from bronchial accumulation, an occasional emetic dose of ipecacuanha may be resorted to with benefit. Under similar circumstances, the persistent use of tartar emetic, in pretty large doses, associated with alcoholic stimulants, is frequently of value. In protracted cases, and during convalescence, tonics are called for, and good nutritious diet. Few drugs are more valuable than opium in the treatment of bronchitis; it relieves pain and distress, diminishes the irritability of the mucous membrane and the need for coughing, and probably also tends to reduce inflammation. At the same time its administration is often fraught with danger. It is generally best to give it in frequent small doses; and it is well to give it very cautiously or to withhold it entirely when the patient shows signs of imperfect aëration of blood, when his bronchial tubes are overloaded with mucus, or when he tends to ramble.

In chronic bronchitis, especially when exacerbations are present, the treatment must in the main be the same as that of the acute affection. On the whole, however, the abstraction of blood, and the use of medicines calculated to depress the patient's strength, are not desirable. Counter-irritants, inhalation, stimulant medicines, tonics, and good diet are chiefly indicated. It is in these cases, too, that hygienic treatment is especially likely to be serviceable. The patient who is suffering from a winter cough, increasing year by year in severity, and in whom emphysema and other such lesions are in progress, should dress warmly even in summer, should be careful not to expose himself to draughts or to the evening or early morning air, should give up those pursuits which expose him to the causes of bronchitis, and should pass his winters on the South Coast, or on the shores of the Mediterranean, or in some other warm equable climate, or else confine himself to a room or suite of rooms, well ventilated, but kept at a uniform and comfortably warm temperature.

---

#### IV. PNEUMONIA

*Causation.*—Inflammation of the substance of the lungs, like bronchitis, is probably due in the large majority of cases to the influence of cold and wet; and it would seem that it may, under special circumstances, be caused either by brief exposure of portions of the heated surface of the body to a severe chill, or by prolonged exposure of the whole normally warm surface to comparatively slight degrees of cold. It is especially common in temperate climates, and at those seasons (spring more particularly) when the temperature is liable to great variations. It may also be caused by the spread of inflammation (whether originally due to cold

or not) from other parts: as from the bronchial tubes, in cases of bronchitis, hooping-cough, measles, influenza, diphtheria, and the like; from the pleura in cases of pleuritis; or, if the pleural cavity be obliterated by adhesions, from the chest-walls or surrounding viscera. And again, it may be developed by the direct action of mechanical or other irritation, such as follows the inhalation of irritant gases, particles of dust or other such substances, solid bodies of larger size, vomited matters, or even water; or it may spring from the presence of emboli in the branches of the pulmonary artery, or of tubercles or clots in the tissue of the lungs.

There are many pathological conditions (especially the presence of pulmonary congestion or œdema, or of specific poisons or effete matters in the blood) which favour the occurrence of pneumonia. And it is probably due to one or other or all of them that pneumonia is so common in the course of heart-disease, kidney-disease, various infectious fevers, erysipelas, rheumatism, and many other inflammatory disorders. It is also apt to occur in persons advanced in syphilis, or worn out whether by disease or overwork.

It must not be forgotten, however, that acute idiopathic pneumonia occurs with considerable frequency amongst those who seem to be in the best of health. This variety of the disease is met with at all ages and in both sexes; but it is more common in men than women, and far more common among the working classes than others—facts which are explicable by the relatively greater exposure to the causes of pneumonia of those who have to earn their livelihood by the sweat of the brow. A previous attack seems to predispose to subsequent attacks.

The influence of micro-organisms in the causation of pneumonia is at present undetermined. Specific bacteria (Friedländer's pneumococcus and Fränkel's diplococcus), sometimes in enormous numbers, have in some cases been detected in the inflamed tissues. This fact, associated with the occasional apparent infectiousness of the disease, renders it probable that at any rate some of the severer forms of pneumonia are septic affections.

*Morbid anatomy.*—It will be convenient, in describing the morbid anatomy of pneumonia, to distinguish, as has generally been done, two forms—namely, *lobar* and *lobular* pneumonia, or, as they are termed by German writers, *croupous* and *catarrhal*. These names are none of them unobjectionable, and it might be better to replace them by the words *diffused* and *patchy*; the type of the former variety being furnished by the idiopathic affection, that of the latter by the condition which is secondary to diseases of the air-passages. The two varieties, however, pass into one another.

A. *Lobar pneumonia* begins with hyperæmia of the small vessels distributed in the walls of the air-cells and bronchial passages; swelling and tendency to proliferation of the epithelial cells of these parts; and exudation of inflammatory lymph (serum, albumen, fibrine), and of the corpuscular elements of the blood. The air-vesicles and passages communicating with them gradually become filled and finally distended with

exuded matter, the air which they contained by degrees gets expelled, and the affected lung-tissue grows solid and heavy. If the parts be now examined microscopically, the dilated blood-vessels will be found to be crowded with their corpuscular contents, and the alveoli full of cells (some merely modified epithelial cells, with one, two or more nuclei, some cells undergoing fatty change, in other words granule-cells, and others having the characters of leucocytes or pus-corpuscles), all blended together into a common mass either by an amorphous glutinous cement, or by a delicate fibrillated network. The ordinary process of inflammatory cell-proliferation has taken place, by means of which the epithelial cells have acquired an embryonic character; and to these, escaped leucocytes have been added. With the progress of the disease the contents of the air-vesicles liquefy, and acquire more and more both the naked eye and the microscopic characters of pus. The fatty degeneration which has been referred to may, either before or after the liquefaction of the contents of the air-vesicles, become general throughout the accumulated cells, which may then, if not expectorated, undergo gradual absorption. The conversion of the inflammatory exudation into pus is occasionally followed by the breaking down of the lung-tissue here and there into abscesses; and occasionally by the occurrence of gangrene. Inflammation of the lung, like inflammation of other parts, rarely if ever takes place without there being more or less abundant serous exudation into the surrounding uninfamed tissues; and, further, pneumonic inflammation tends, like most inflammations, to spread.

The progress of pneumonia through its various phases is quite gradual; nevertheless, there are at least three stages which severally present more or less obvious characteristic features. The first of these is the stage of *engorgement*, the second that of *red hepatisation*, and the third that of *grey hepatisation*. In the first stage the lung still contains air, though in diminished quantity; it is deeply congested, exudes more moisture than natural, is increased in weight, and is more easily lacerable than healthy lung-tissue. This is the period of congestion and commencing proliferation; and at this time the condition of the lung is scarcely, if at all, distinguishable from that of simple hypostatic congestion. In the second stage the lung is consolidated; it has lost its air, and its cavities are filled with coherent masses of cells; it is distended to its full size, and its constituent lobules are distinctly mapped out upon the surface; on section it appears to be pretty dry and slightly granular (a condition still more noticeable on the surface produced by laceration); and it presents a peculiar marbled aspect which is due to the intermixture of nearly colourless inflammatory deposit, patches of congestion, and the irregular slate-coloured or black tracts which commonly stud the lung-tissue of persons who have reached adult age. The general hue of the lung is for the most part somewhat pale; there is probably, however, more decided congestion during life, and even after death the tissue is in some cases almost as deep in hue as we find it in pulmonary apoplexy. Sometimes, indeed, there is actual extravasation of blood. The lung-tissue

is easily torn, and readily sinks in water. The third stage differs from the second, mainly in the assumption by the affected lung-tissue of a pretty uniform opaque greyish, yellowish or greenish tinge, in its largely increased friability, and in the ready exudation from the cut surface of thick, turbid, purulent fluid. In some cases the fluid is comparatively scanty ; in some it is so abundant that the lung is like a sponge saturated with pus.

We have already mentioned that there is generally, if not always, considerable cedema of the lung-tissue beyond the part actually inflamed. There is also almost invariably a deposit of inflammatory lymph on the surface of the inflamed portion of lung, as well as upon the parietal pleura in contact with it, which tends to diffuse itself over the serous membrane, more especially towards its base, but is not generally attended with any large amount of serous effusion.

Since pneumonia tends to spread, it naturally follows that different portions of affected lung often present well-marked differences of condition, and that we occasionally find all the recognised stages of pneumonia present at the same time in the same case. Inflammation may involve the lung to very various extents : thus it may be limited to a patch no larger than a walnut, or may include an entire lobe or even a whole lung ; and, further, it may affect both lungs. It is curious how often it is strictly limited by the fissures or fibrous septa which separate lobes, and how often it is accurately mapped out by the margins of lobules. As regards position, it seems to be a well-established fact that the right lung is more frequently affected than the left, and the lower lobe than the upper. In reference to the latter point, however, it may be observed, that if we divide the lung horizontally midway between apex and base, there will be at least some two or three times as much lung-tissue below as there is above the plane of division, and that hence, if all parts of the lung be equally liable to inflame, inflammation of the upper part should be several times less frequent than inflammation of the lower part. The forms of pneumonia which supervene on hypostatic congestion, or come on in the course of renal and cardiac disease, or complicate pulmonary apoplexy and tubercle, differ little anatomically from that which has here been described.

*B. Lobular pneumonia* is especially the pneumonia of young children ; it is not unfrequent, however, in older persons. In its best-marked form the lung is studded with pneumonic patches, varying in size from about that of a pea to that of a filbert, and involving each one or more pulmonary lobules, circumscribed by the interlobular septa, and separated from one another by a network of still crepitant, and it may be healthy, lung-tissue. The pneumonic patches may be in the condition of engorgement simply, in which case their character may possibly fail to be recognised ; or they may present the ordinary features of red or grey hepatisation. Further, by extension of disease, neighbouring patches may coalesce, and thus extensive tracts of lung-tissue become involved. Lobular and lobar pneumonia here pass into one another. True lobular pneumonia is always secondary to the blocking up of air-passages, and

especially those of capillary size; and it may be excited immediately either by the gradual extension of the inflammatory process from the tubes to the air-vesicles, or by the entrance into the vesicles during inspiration of inflammatory products of the tubes, which then act as irritants. But, whatever the cause, we find in the inflamed parts not merely overgrown and modified epithelial cells, but also, according to the stage of the disease, granular and embryonic cells in greater or less proportion. The connection of lobular pneumonia with obstruction of tubes is further shown by the facts, that lobular collapse is often associated with it, and that then the collapse and pneumonic conditions may often be seen to pass into one another by gentle gradations.

Closely related to lobular pneumonia is the disseminated pneumonia due to obstruction of small branches of the pulmonary artery, either by embolism or thrombosis, or in the course of pyæmia. In these cases, as in the other, the affected patches are usually of small size, and limited by the margins of lobules. But there is greater variety of result, especially in pyæmia; in which, while the patches sometimes present simple engorgement, or red or grey hepatisation, they not unfrequently are the seat of hemorrhage, or undergo rapid suppuration or gangrene. Lobular pneumonia is generally best marked towards the basal portions of the lungs, and the superficial patches are often the centres of areas of pleural exudation.

In all forms of pneumonia, even in such as are not of bronchitic origin, there is a tendency to the development, sooner or later, of bronchitis. But, apart from this, there is a marked disposition, early in the course of pneumonia, to the effusion into the tubes from the inflamed air-cells of a transparent, very viscid fluid, uniformly stained with blood, and containing corpuscular elements; and, in some rare cases, this effusion, like that in the air-cells, whence it is derived, undergoes coagulation in the bronchial tubes, which thus become filled to a greater or less extent with casts consisting of coagulated fibrine and corpuscles.

Notwithstanding the frequency with which pneumonia proves fatal, it does not often go beyond the third of the stages which we have described; sometimes however, abscesses form, sometimes gangrene takes place, and sometimes the pneumonia lapses into a chronic condition. Pneumonic abscesses are usually of small size and irregular form; and in some cases, especially when they are developed in connection with lobular pneumonia, the terminal bronchial tubules are primarily affected, their parietes become destroyed, and the abscesses taking their course assume a dendritic character. Gangrene seldom occurs in simple idiopathic pneumonia; it is chiefly met with in those cases in which the pneumonia is secondary to or complicated with some other affection. It is characterised by the breaking down of the lung-tissue into a fetid dirty greenish-yellow pulp, and by greenish discoloration of the consolidated tissues around. Not unfrequently the latter are cedematous and present a slightly translucent aspect. The gangrenous condition may involve either an extensive

tract of lung-tissue or several scattered patches, or even a single small patch. If it be recent at the time of post-mortem examination its margins will be found ill-defined; if it have existed for some length of time the gangrenous cavity will probably be bounded by a well-defined edge. Of chronic pneumonia we shall speak at length hereafter.

Of the associated morbid phenomena of pneumonia there are several that call for mention, if not for detailed description. We have adverted to the co-existence with it of pleurisy and bronchitis; but, besides these, we often observe an herpetic eruption on, or in the neighbourhood of, the lips; jaundice without obvious hepatic disease; intestinal congestion, with sometimes membranous patches on the mucous surface of the large intestine; and inflammation of the bronchial glands. Further, the conditions which give rise to pneumonia occasionally give rise at the same time to inflammation of other organs. Thus accompanying pneumonia we sometimes find inflammation of the brain, kidneys, bowels, or pericardium. It is common, after death, for the right side of the heart to be full of fibrinous coagulum which is prolonged into the pulmonary artery, while the left side of the heart is contracted and almost empty.

*Symptoms and progress.*—Idiopathic pneumonia is frequently ushered in with a day or two of feverishness or undefinable feeling of illness. The invasion of the disease is generally marked by a sudden and severe rigor, or a succession of rigors, or in children by an attack of convulsions—phenomena which are attended with a rapid and considerable elevation of temperature, and the usual symptoms of inflammatory fever. The specific signs of the pulmonary affection usually declare themselves immediately or in the course of the next four-and-twenty hours; very rarely they are delayed for a still longer period. They consist in rapidity and shallowness of breathing, with dyspnoea; dorsal decubitus; cough soon attended with blood-stained glutinous sputum; pain probably in the affected side on drawing a deep breath; and, according to the stage which the pulmonary affection has reached, fine crepitation, or dulness with tubular breathing, and augmented bronchophony and vocal fremitus. While these local conditions are in progress, the patient's febrile state continues; his skin is hot and dry or perspiring, his tongue furred, his pulse accelerated; jaundice is apt to come on, and diarrhoea; his urine is scanty and perhaps albuminous; at the same time, probably, he suffers from hebetude, with delirium, which shows itself chiefly at night. The further progress of the case varies according to its severity. In very mild cases, after two or three days of illness, the patient's temperature falls, his other symptoms subside, and convalescence is established. In other favourable cases convalescence may be delayed for a week, ten days, or a fortnight; and the amendment may then be either sudden or gradual. In cases which end fatally, death may occur at any period of the disease, even during apparent convalescence, and is due, as a rule, either to asthenia or to gradual asphyxia, or to a combination of these conditions.

We will discuss *seriatim* some of the more important of the phenomena which attend pneumonia.

The respirations are usually hurried and shallow, and may vary in rate from the normal up to 50, 60, or even 70 and upwards in the minute; when very rapid they are usually attended with a sucking sound in the mouth, and expansile movements of the *alæ nasi*; there is often, but by no means necessarily, more or less severe dyspnœa, and generally there are signs of breathlessness when the patient attempts to speak.

Cough, which is sometimes very troublesome and even paroxysmal, is almost always present. It is at first dry, but is soon attended with the expectoration of transparent and very viscid mucus, tinged with the colouring matter of the blood. This is usually said to have a rusty tint, and indeed often has; but it varies in colour between a pale saffron and a bright vermilion, and in the latter case may be mistaken, on hasty inspection, for pure blood. After retaining this character for a few days, the expectoration loses its sanguineous tint and becomes opaque and greenish (acquires in fact a muco-purulent character), and then gradually diminishes in quantity. In some cases, instead of undergoing this, which may be regarded as the normal change, it acquires a deep purplish or reddish-brown tint and at the same time a more watery consistence. This form of sputum has been likened to prune-juice, and is generally a sign not only of increased congestion and escape of blood, but of the access of the third stage, and of an unfavourable issue. In some cases, again, the expectoration becomes distinctly purulent, or is attended with the horrible fetor which usually indicates pulmonary gangrene. The quantity and quality of the expectoration vary remarkably in different cases. In some there is absolutely none from first to last; in some the patient never coughs up more than one or two rusty-coloured sputa; in some the expectoration, even if abundant, never presents the characteristic tint. Pneumonic expectoration is characterised by the presence of a superabundance of common salt, and contains a considerable quantity of mucus and albumen.

There is much variety as to the presence and degree of thoracic pain. In some cases there is no pain whatever; in some there is a mere sense of heat; in some the patient has severe stitch whenever he coughs or draws a deep breath. This pain is pleuritic in character, and doubtless due to the co-existence of pleurisy.

In the first stage of the disease the most characteristic auscultatory phenomenon is minute crepitation, which may be audible during the whole of inspiration, sometimes during expiration as well, and not unfrequently only at the end of a deep inspiration, such as that which precedes a cough. In association with this there may be no change on percussion, or there may be high-pitched resonance or *bruit de pot fêlé*. The second stage is marked by the supervention of dulness over the consolidated portion of lung, with increase of vocal fremitus; cessation of fine crepitation, and the development in its place of well-marked tubular breathing; bronchophony; and in some cases pectoriloquy. There may also be sharp metallic crepitation or rhonchus. In some cases (probably when the bronchial tubes leading to the consolidated portion of lung are completely

obstructed) there is almost total absence of respiratory sounds and bronchophony over the affected region. In consequence of the co-existence of pleurisy it is common to get friction-sounds mixed up with those due to pneumonia; and it is not uncommon even for the pneumonic signs at the lower part of the chest to be suppressed or replaced by the phenomena indicative of pleurisy. At a later stage, when lung-tissue is breaking down, or resolution is taking place, tubular breathing gives way to a kind of coarse crepitation, to which the name of *crepitus redux* has been given. This gradually passes into the ordinary bronchitic râles. It may be added that when the pneumonic lung is consolidated, the movements of the thoracic walls in relation with it become impaired, and the resistance on percussion manifestly increased; and, further, that pneumonia may be present, deep-seated in the lung, or limited to its diaphragmatic or inner surface, and thus altogether escape detection by auscultation or percussion. Some degree of dulness on percussion usually persists long after the disappearance of the other local signs of pneumonia.

The cardiac pulsations are always increased in frequency during the febrile stage of the disease, but rarely increased proportionally to the respirations. Often indeed their ratio, instead of being about 4 to 1, sinks to 2 or  $1\frac{1}{2}$  to 1. In adults the pulse usually ranges from 80 to 120, but it may reach 180 or more; in children it is generally more rapid, and may rise to 200 and upwards. Extreme rapidity is generally associated with feebleness, and not unfrequently with irregularity, and is hence to be regarded as an unfavourable sign. In the beginning the pulse is often somewhat full and strong, but sometimes full, soft, and dicrotous; later on it always becomes feeble and dicrotous. During convalescence it may fall below the normal frequency. While pneumonia is in progress the systemic veins are apt to get over-loaded, and the surface may assume a dusky hue. The blood always presents a large excess of fibrin.

The tongue is coated, and in some cases becomes dry and brown, and sordes accumulate upon the teeth. Thirst is pretty constant; there is always loss of appetite, and occasionally sickness. The bowels vary; sometimes they are not particularly affected throughout the disease; sometimes they are constipated; sometimes, on the other hand, there is diarrhoea, and this may be dysenteric in character. The occurrence of jaundice during the progress of pneumonia is neither uncommon, nor very important. It is said to occur most frequently in those cases in which the right lower lobe is affected. But there is no more necessary connection between right pneumonia and jaundice than between left pneumonia and it.

The urine is scanty, dark-coloured, and of high specific gravity, presenting a diminished quantity of chloride of sodium and a great excess of urea and uric acid, with a tendency to the deposition of urates. Sometimes it contains also a little albumen, with hyaline, granular, or epithelial casts, and even blood. During convalescence it gets much more abundant, pale, and of low specific gravity; and the urea undergoes diminution, while salt increases.

The face is flushed in the early period of pneumonia, and may even be somewhat livid; the skin generally is hot and dry; but profuse sweats are not uncommon during the progress of the disease, and generally attend its decline. An herpetic eruption about the lips and *alæ nasi* is almost pathognomonic.

The patient at first complains of headache and general febrile pains. He is often drowsy, yet, at the same time, restless, especially at night-time. Delirium is apt to come on early, at first being limited to the night, but subsequently becoming more or less constant. In some instances, and mainly in persons who have been given to drink, the nervous symptoms soon assume all the characters of delirium tremens. And again, patients, not otherwise obviously affected in mind, occasionally get suddenly and violently maniacal, the paroxysm possibly abating as suddenly as it arose. In fatal cases delirium is apt to pass into coma. Muscular tremors and subsultus, with loss of control over the bladder and rectum, are frequently observed in severe cases.

The temperature rises rapidly from the time of invasion, so that within a few hours, at most perhaps twelve, it has almost attained its maximum; this varies from  $100^{\circ}$  to  $106^{\circ}$ , or even more. Thenceforward the temperature remains high, probably increasing somewhat, with morning remissions and evening exacerbations, until the time of commencing convalescence, when it suddenly or gradually falls. In the former case it may sink to the normal or below it in the course of twenty-four hours. Occasionally in fatal cases the temperature rises rapidly before death.

The symptoms of uncomplicated idiopathic pneumonia are collectively so characteristic of the disease that it is almost impossible to mistake their significance. The affections, other than those of the respiratory organs, with which it is most liable to be confounded are typhus and enteric fever. No real difficulty, however, can arise unless the specific characteristics of these fevers be in abeyance, and they be at the same time (as they often are) complicated with secondary pneumonia.

It is altogether different, however, in respect of the various forms of intercurrent or secondary pneumonia, and of the lobular variety of the disease. These creep on, for the most part insidiously, in the course of other grave affections, which have already probably produced serious pulmonary symptoms, such as dyspnoea, cough, expectoration of serous, mucous, or bloody sputa, lividity of surface, and other indications of embarrassed circulation and carbonic acid poisoning; their onset is not usually marked by rigors or anything equivalent to rigors, nor is their progress usually attended with the high febrile disturbance which characterises the idiopathic variety; and, again, they are not often accompanied by labial herpes, or jaundice, and very often there is, excepting towards the close of the disease, an entire absence of delirium. The supervention of these forms of pneumonia may be suspected in patients suffering from the various diseases which are apt to be complicated by them, when their symptoms, and especially those referrible to the respiratory organs, be-

come aggravated ; but they can only be positively determined by careful physical investigation of the condition of the thoracic organs. It must not be forgotten, however, that lobular pneumonia may be present to a considerable extent without producing the characteristic dulness, the tubular breathing, or the other specific signs of the more uniformly diffused variety of the disease. The auscultatory and percussive phenomena indeed may differ little if at all from those which attend capillary bronchitis.

The breaking down of portions of lung-structure which occasionally attends the later stage of pneumonia does not reveal itself by any special sign, unless the cavities be such as, from their size or position, to give rise to characteristic auscultatory phenomena. In rare cases such abscesses burst into the pleura, or (the lung being adherent) perforate the thoracic walls, or form sinuses running down behind the peritoneum, and opening ultimately into the colon or one of the hollow viscera of the pelvis. The occurrence of gangrene is usually revealed by the disgusting fetor of the breath, especially during the processes of coughing and expectoration, and in a less degree by the look and smell of the sputa. Here also the cavities due to the destruction of lung-tissue may perhaps admit of detection. The presence of gangrene is generally attended with marked depression of the vital power, or in other words, collapse.

Pneumonia is always a disease of considerable gravity. Still, in its idiopathic form, it comparatively rarely kills, unless the portion of lung involved be extensive, or both lungs be attacked, or except in the case of persons advanced in years, or of those whose constitutions have been injured by long-continued bad habits, overwork, or disease. The secondary form of the disease, and especially the lobular variety, on the other hand, are exceedingly fatal, and may be included among the chief immediate causes of death in the various maladies which they complicate.

*Treatment.*—There are few diseases for which so many opposite plans of treatment have been employed with reputed success as for pneumonia. It is a disease, too, which, more perhaps than any other, has on this very account been appealed to in proof of the change of type of disease. From the time of Laennec to about the middle of the present century almost implicit reliance was placed in the combined use of blood-letting, antimony, and mercury. Since then, especially dating from the time of Dr. Todd, these remedial agents have been to a large extent discarded, and have got replaced by the free exhibition of alcoholic stimulants. Many, indeed, now regard all medicinal treatment as of little or no importance ; and it is quite certain that a large number of even severe cases recover perfectly if left to nature and the nurse.

In the majority of cases of the idiopathic disease it is probably sufficient to keep the patient in bed in a comfortable, well-ventilated room, of medium temperature ; to relieve thoracic pains with mustard plaisters and the like ; to assuage febrile thirst by the exhibition of soda-water, orangeade, or lemonade ; to support strength by the frequent administration of

milk or gruel, or some equivalent nutritious fluid; and to relieve, from time to time, by simple measures, diarrhoea or constipation, and other remediable derangements of the various organs; and then, as convalescence comes on, to give vegetable tonics, and gradually to improve the diet in respect of both quantity and quality. It is doubtless true, however, that in many cases the above plan of treatment may be judiciously supplemented by other measures. Bleeding from the arm, or the local abstraction of blood from the chest by cupping or leeches, is certainly followed by relief to symptoms when employed early in cases in which there is high fever and much dyspnoea. We believe that bleeding from the arm is more efficacious than the other methods of bleeding, but in any case it is better to remove sufficient blood at a single operation than to be called upon to repeat it. Counter-irritants and detergents are often serviceable at a later period of the disease, or at the beginning of slight cases in which bleeding is not deemed necessary. They relieve pain, and sometimes diminish difficulty of breathing. Dry cupping is of much value. Some physicians think it well to keep the affected side invested in a large poultice or a layer of cotton-wool; others prefer the application of ice-bags or cold compresses. We do not think that any benefit accrues from the former plan, but the latter probably has some advantage. Expectorants, such as ipecacuanha in small doses, may possibly aid those cases in which there is frequent and troublesome cough, with difficulty of expectoration; and, under the same circumstances, the addition of a small quantity of opium may be serviceable.

When the pulse gets very quick and weak, and delirium is established, especially if the patient present the general symptoms of delirium tremens, diffusible stimulants, such as ammonia, and alcoholic drinks, in quantities to be determined by their effects, are indispensable. With the object of reducing temperature, various agents have been recommended; and possibly one or other of them may sometimes be used with advantage; among these may be enumerated cold baths, antifebrin, quinine in large doses, salicylic acid, digitalis, and aconite. The occurrence of suppuration or gangrene is a special reason for the maintenance of the patient's strength by nutritious food, stimulants, and tonic medicines. Opium is often of great service, but should not be given, or should be given very cautiously, when the patient is suffering from dyspnoea and insufficient aëration of the blood. The treatment of secondary pneumonia merges in the treatment of the disease it complicates. Its supervention, however, is on the whole a plea, not for depletion, but for the use of stimulants and nourishment.

---

## V. PLEURISY (*Pleuritis*)

*Causation.*—Pleurisy is either idiopathic, or the result of local irritation. The former class of cases includes pleurisy arising directly from exposure to cold (the form of pleurisy which corresponds to idiopathic pneumonia and bronchitis) and that which takes place in the course of

acute rheumatism. Among the latter class may be enumerated, pleurisy due to extension of inflammation from inflammatory and other affections of the lungs, or thoracic parietes; that due to mechanical injuries, more especially to the rupture into the pleura of pulmonary cavities, or of abscesses of the liver or other neighbouring organs; as also probably the pleurisy so commonly associated with the progress of pulmonary phthisis and thoracic carcinoma. In addition to the varieties of pleurisy here enumerated must be mentioned those which are developed in the course of small-pox, scarlatina, enteric fever, pyæmia, albuminuria, and heart-disease, and in respect of which these several affections act variously, sometimes as exciting, sometimes, and perhaps more frequently, as predisposing causes.

*Morbid anatomy.*—Inflammation of the pleura, like that of all other serous membranes, commences with hyperæmia of the blood-vessels, proliferation of the protoplasmic elements of the tissues, more especially the epithelium, and effusion of inflammatory lymph, comprising various but pretty considerable quantities of albumen, fibrine, and corpuscles. The last two for the most part remain adherent to the surface, forming the so-called ‘false membrane;’ the fluid, containing albumen, fibrine, and a variable proportion of corpuscles, accumulates within the serous cavity. The inflammatory process combines, therefore, three elements, which may conveniently be considered independently of one another, namely: first, hyperæmia and infiltration of the serous and sub-serous tissues; second, the formation of a false membrane; and, third, the effusion of serum.

The first of these elements is the first in order of development; but it seldom attains a high degree or forms a prominent item in the collective inflammatory changes. There is always, however, more or less obvious infiltration—its amount having some relation to the intensity of the inflammatory attack; and this not unfrequently extends into the connective tissue round about, as, for example, along the interlobular septa of the lungs, and into the tissues of the mediastina, diaphragm, and external thoracic parietes. And thus it occasionally happens that the superficial stratum of lung-tissue becomes involved, that the diaphragm and intercostal muscles suffer, and that inflammation, commencing in one serous cavity, extends to those in its immediate vicinity.

The effusion of inflammatory lymph always begins early. At first this constitutes an exceedingly thin, granular, but more or less coherent pellicle, the presence of which renders the serous surface obviously rough to the finger and deprives it of its polish. This gradually extends in area and increases in thickness, usually becoming at the same time more and more yellow and translucent. The thickness which it may attain varies roughly from that of a mere film up to half an inch or even an inch. The character of its surface presents numerous varieties, which depend partly on the tendency of the lymph itself to be deposited in the form of a network, partly on the attrition to which it is exposed during the movements of the opposed surfaces upon one another, and partly on its stickiness. It thus

acquires a more or less irregular ribbed, villous, or retiform character. When the opposed surfaces of an inflamed pleura are separated by fluid effusion it often happens that trabeculae and bands or septa of inflammatory lymph pass irregularly between them. The attached surface of the false membrane is always closer in texture and tougher than its free surface, and becomes with age more and more firmly united to the proper serous membrane, with which indeed it ultimately gets incorporated. It is here, too, that organisation, with the formation of new blood-vessels, commences—a process which, if the case go on favourably, ultimately pervades the entire thickness of the false membrane, and leads to the blending of the opposed layers, their conversion into connective tissue, and the obliteration of more or less of the pleural cavity.

The fluid effusion varies greatly in quantity relatively to the other two products of the inflammatory process. It is difficult in many cases to account for this fact, but occasionally it is explicable in some degree on mechanical grounds. In the first instance the fluid is transparent, yellowish or greenish, and probably presents flakes of lymph floating in it. In many cases it retains this character throughout; but in some it becomes turbid or opaline, and deposits a little milky sediment on standing. Occasionally it acquires the characters of ordinary pus. It may be added that blood is sometimes extravasated, either from rupture of the new-formed vessels of the false membrane or from ulcerative destruction of the subjacent lung-tissue; that gas is occasionally present—an occurrence due either to an external wound or to some communication between the lung or intestine and the pleura; and, lastly, that the purulent contents occasionally get fetid. The quantity of fluid effused may vary from almost zero up to three or four quarts.

In a large number of cases, especially those in which the pleurisy is due to the extension of inflammation from subjacent parts (as for example, when it arises in the course of peritonitis, pericarditis, lobar pneumonia, or the various forms of disseminated pneumonia), the discharge of serum is very scanty, and the lymph forms a thin film, which may be limited to the area primarily involved, and that opposed to it, or may gradually creep over the whole pleural surface. Moreover, in such cases it is far less liable to spread from below upwards than from above downwards; but generally even in slight cases with little effusion it is common for the inflammatory products (solid as well as fluid) to subside to the most dependent part of the pleural cavity and to accumulate there.

In other cases, and more particularly, perhaps, in the idiopathic form of the disease, in those varieties of it which attend small-pox and other eruptive fevers, or tuberculosis, and in that due to perforation of the pleura by abscess, effusion takes place rapidly and copiously. The effects of the accumulating fluid are the distension of the pleural cavity, the compression of the lung, and the displacement in different degrees of the surrounding organs. As the fluid rises in the thorax, more and more of the lung, commencing with its lower part, has its air squeezed out of it. Subsequently, perhaps, the whole organ suffers, and consequently be-

comes remarkably reduced in size, and compressed into the neighbourhood of its root and the upper part of the angle between the vertebræ and ribs. There, in fact, it may lie concealed from view by a layer of lymph continuous with that lining the thoracic parietes; and the unskilled pathologist might at first sight readily assume that the lung had undergone total destruction. If the lung have been the seat of consolidation, or if it have been previously bound to the parietes here and there by old adhesions, or if the distension of the pleura with fluid be incomplete, the compressed lung will probably hang or protrude more or less irregularly into the pleural accumulation. The abundant presence of fluid causes, in addition to compression of the lung, displacement of the heart and mediastinum towards the opposite side (especially observable when the left pleura is affected), depression of the diaphragm, and expansion of the outer parietes of the thorax, with widening and probably bulging of the intercostal spaces.

When suppuration (*empyema*) takes place (a frequent occurrence in the pleurisy of small-pox, scarlet-fever, measles, and pyæmia, and in that of women who have just undergone childbirth, and from perforation), all the phenomena just described naturally ensue; but others due to the presence of pus are probably superadded. The abscess sooner or later tends to point. Not unfrequently it opens into the lung; and often it makes its way through the thoracic parietes, forming, in the first instance, a sinus between the ribs, which probably become exposed and carious, then an accumulation between the ribs and integuments, which, gradually enlarging, may, ere an external opening takes place, develop into a large superficial abscess. The route which such a sinus may take, and the point at which it may present, are liable to great variety. Thus sometimes the abscess appears at the upper part of the thorax and even above the clavicle; sometimes it opens in the loin below the level of the twelfth rib. Much more frequently, however, it occupies some intermediate position. In rare cases the empyema perforates the diaphragm, and it may then take the course of a renal or psoas abscess, and finally open in any of the situations in which such abscesses are liable to open.

The ultimate consequences of pleurisy are various. In the great majority of cases the fluid accumulation undergoes absorption, the partially-compressed lung recovers itself, and the effused lymph is slowly converted into a kind of cicatricial connective tissue, which remains permanently. This may ultimately constitute a mere white opacity upon some portion or portions of the pleural membrane; or, what is far more common, result in the formation of adhesions between the opposed surfaces. The latter may consist in a mere intervening film of connective tissue, or in groups of filaments and bands of various lengths, or in tissue as close, dense, and tough as cartilage or tendon, and which in process of time may become the seat of calcareous deposit. Adhesions may be limited to one or two points only, or may be generally but irregularly distributed, or may involve the whole extent of the pleura, the cavity of which then ceases to exist.

When the lung has long been compressed by fluid (whether serum or pus), and rendered entirely airless, especially if at the same time it has been covered with a thick dense layer of false membrane, the absorption or removal of the fluid is probably attended with little or no restoration of the lung; and the space which that organ occupied becomes filled up by the falling in of the surrounding parts. The mediastina and the heart are drawn over towards the affected side; the corresponding half of the diaphragm rises, carrying with it the stomach or liver, as the case may be; the ribs get retracted, and approximated; the shoulder falls; the spine bends in the same direction; and the patient's carriage undergoes a corresponding change. At the same time the adhesions probably remain abundant and thick, and sometimes oedematous. In many cases, on the other hand, when compression has been less complete, or the adhesions are less strong, convalescence, even after an extreme amount of pleural effusion, is attended with more or less restoration of the affected lung—an event which often requires considerable time for its completion. In some such cases when death has ensued before the entire removal of the fluid, the lung is found to be invested in a fenestrated layer of pretty dense false membrane, which by the general pressure it exerts renders the organ irregularly rounded, while the fenestræ permit of irregularly distributed lobulated protrusions of crepitant lung-tissue.

An empyema may, after the discharge of its contents, be followed by any of the consequences above enumerated; but, like other deep-seated abscesses, its cavity often fails to get wholly obliterated, and a sinus results, through which it continues to discharge for an indefinite period. This tendency for an empyema to remain open is occasionally traceable to a carious condition of the ribs. On the other hand, circumscribed collections of pus here as elsewhere sometimes dry up into caseous masses.

Lastly, inflammation may attack a pleura already partially or wholly obliterated by adhesions. In the latter case the consequences will probably be congestion, infiltration, and thickening of the pre-existing false membrane. In the former case the effused serum or pus will occupy either a more or less definitely circumscribed space or the whole pleural cavity, divided by bands and septa into a series of inter-communicating loculi. Such limited accumulations of fluid are occasionally met with in the interlobar fissures, or between the diaphragm and base of the lung, or between the inner aspect of the lung and the mediastina—situations in which they often escape recognition during life; or even at the upper part of the chest. Their usual seat is below.

*Symptoms and progress.*—The symptoms of pleurisy present great variety, both in intensity and in kind—the differences being due mainly to differences in the extent, position, and intensity of the inflammation, in the circumstances under which it is developed, in the diseases with which it is associated, and in the stage at which it has arrived. The specific symptoms nevertheless are simple enough, and in addition to the signs furnished by percussion and auscultation, principally comprise thoracic pain during respiration, dyspnoea, and inflammatory fever.

The invasion of idiopathic pleurisy is far from uniform in its symptoms. In some cases the patient complains only of a little feverishness, loss of appetite, and general malaise, together with a stitch or pain in one side when he breathes deeply, or coughs, or twists his body or moves the corresponding arm; and he may continue to follow his ordinary avocation, until, in the course of a week or two, or more, he is restored to health, or until, at the end perhaps of an equally long time, increasing illness and difficulty of breathing make him consult a medical man, who may possibly then find the implicated side distended with fluid. In other cases the beginning of the disease (even if there be little fever and the attack prove to be a mild one) is attended with such intense pain in breathing and moving, such rapid, shallow, and gasping respiration, and so much appearance of distress, that it is difficult not to believe that the patient is in extreme and immediate danger. In other cases he is suddenly seized with rigors, or (and this may occur even in adults) an epileptiform attack, followed by high febrile symptoms and the characteristic stitch. In other cases, again, after he has complained for a day or two of some degree of feverishness, and pain in the side, the symptoms, both local and febrile, assume sudden intensity.

But, however the disease comes on, whether with rigors or with none, whether slowly or insidiously or by sudden onset, it rarely happens, unless it be suppurative from the beginning or dependent on the presence of some blood-poison, that the temperature rises above  $102^{\circ}$ ; often, indeed, it does not exceed  $100^{\circ}$ ; and it may be scarcely above the normal. The condition of the pulse and the other general symptoms bear some relation to the temperature. The pulse is generally full and vibratile or dicrotous, and somewhat increased in frequency, the skin is hot, the tongue furred, the appetite impaired, the thirst increased, the urine scanty and high-coloured, and the bowels confined. There are probably also headache and general febrile pains. From the beginning the patient has a stitch which is usually referred to the mammary region, and the presence of which renders deep inspiration and all thoracic movements painful, so that the breath becomes hurried, shallow, perhaps irregular, and frequently attended with an expiratory groan, and the patient avoids all unnecessary movement. There is usually also some tenderness on pressure and percussion of the affected side.

While these symptoms are present and the pleurisy remains in the so-called 'dry stage,' percussion may perhaps reveal some little dulness at the base of the pleural cavity, and auscultation may detect, here or elsewhere, some variety of friction sound. Cough is often absent, and when present, dry, or attended only with a little frothy expectoration. It is rarely severe, but is sometimes paroxysmal and troublesome, and always painful.

As effusion increases, the pleuritic stitch for the most part diminishes, and may at length wholly disappear. Meanwhile the febrile temperature and general symptoms of illness may remain at the same level, or undergo some diminution. Dyspnœa may or may not increase; and it is an im-

portant fact that the effusion of sufficient fluid to distend the pleural cavity is in some cases attended with little or no obvious dyspnœa so long as the patient remains at rest. On the whole, however, dyspnœa increases with increase of fluid accumulation; and the patient not only breathes rapidly, but suffers from much distress and anxiety, gets pale or livid, even to cyanosis, and presents all the phenomena of slow asphyxia. The presence of fluid in the pleura is indicated : by dulness on percussion up to the level at which the fluid stands—the level, in many cases, distinctly varying, in relation to the different points of the thoracic walls, with the patient's movements; by suppression of vocal fremitus over the dull part; and generally by absence of respiratory sounds over the same region. Faint tubular sounds, however, or even an indistinct vesicular murmur is often audible. Ægophony is usually to be heard about the angle of the scapula; sometimes, also, marked and loud tubular breathing about the upper margin of the fluid behind; frictions-sounds above the level of dulness, especially in front; and high-pitched resonance or the *bruit de pot fêlé* over the uncompressed portion of lung.

When the effusion fills the pleural cavity, and the lung is wholly compressed, dulness of the side, with absence of vocal fremitus, becomes general, and both ægophony and respiratory sounds disappear more or less completely. The last, however, may generally still be heard about the apex, in front and behind, and thence downwards behind, between the scapula and spine; and occasionally, indeed, they remain very feebly audible over nearly the whole of the affected side. But, in addition to these phenomena, the heart becomes displaced, the diaphragm thrust down, the side distended and almost immovable, with dilated intercostal spaces, over which, by careful manipulation, fluctuation may sometimes be detected.

Convalescence may commence at any stage. In a large proportion of cases, the patient begins to recover before there has been any obvious effusion of fluid; pain in the side gradually ceases, febrile symptoms (if there be any) subside, and friction slowly vanishes. In other cases convalescence does not commence until after fluid has accumulated, and more or less of the lung has been compressed. Here, again, convalescence is indicated by subsidence of fever and general improvement in the condition of the patient's bodily functions; his breathing becomes more natural, and his appetite returns. At the same time the effused fluid is gradually absorbed, the pleural surfaces come again into contact, and consequently pain may return temporarily and friction be re-established. Indeed, friction is often a more marked phenomenon of convalescence than of the early stage of the disease. It may happen that, with the disappearance of the fluid, the lung enlarges, and healthy respiratory sounds are speedily restored; but, even in favourable cases, it is usually a long time (it may be months) before friction wholly disappears, and even longer before resonance and respiratory sounds return to the basal portion of the affected side of the chest. In less favourable cases, the lung is restored in part only, or remains permanently collapsed. Then all those changes

in the form of the side and arrangement of internal organs, which have already been described, ensue. But even here some improvement may be hoped for in the course of years. The patient, however, usually remains weakly and short of breath.

The common cause of death in simple pleurisy is asphyxia due to the pressure of the accumulated fluid; the patient may die, however, from syncope or asthenia, and in either case death is apt to take place suddenly.

The supervention of suppuration (the development of empyema) is often insidious and unattended with either the aggravation of old symptoms or the occurrence of new ones. The simple long persistence of copious effusion affords presumptive evidence of suppuration. Suppuration is generally indicated also when there has been, from the beginning of the attack, much fever, and rapid filling of the side with fluid; and especially when, in the course of a case hitherto of only moderate severity, rigors occur, and fever, becoming greatly augmented, continues augmented. The local indications of empyema are not necessarily more pronounced than the general symptoms. In addition to those of distension from mere accumulation, we sometimes observe general or partial œdema of the integuments on the affected side, sometimes distinct bulging of the intercostal spaces, sometimes unnatural distinctness of the superficial veins, and sometimes a circumscribed redness and induration, or a fluctuating swelling superficial to the ribs, due to the escape of matter from the pleural cavity through an intercostal space into the soft tissues beneath the integuments. We have pointed out that an empyema may burrow in almost any direction and discharge itself at almost any surface; the most important practical terminations of this kind, however, are by perforation of the lung and by perforation of the thoracic parietes. In the former case the patient suddenly expectorates a large quantity of pus, and may continue henceforth to discharge pus either continuously in comparatively small quantities, or at irregular intervals profusely. In the case of discharge through the thoracic parietes, the abscess first points, and then opens either spontaneously or by operation, and as in the former case pus, in more or less abundance, escapes, and probably continues to escape. The sudden expectoration of pus, or the appearance of an abscess in the thoracic walls, is sometimes the first clear indication that there has been a circumscribed empyema. But it must not be forgotten that a superficial abscess often communicates, by a comparatively long and tortuous passage, with the internal abscess which gave it origin; and that hence (in the case of circumscribed empyema) it may be impossible to trace it back to its source, and make sure of its empyematic origin. Thus an abscess of the lower part of the pleura may be readily and pardonably mistaken for a perinephric or lumbar abscess. The progress of a discharging empyema is, as has already been pointed out, apt to be very chronic, especially if the original cavity were large—the discharge then often becoming fetid; and, in dependence mainly on the copiousness of the discharge, the patient becomes emaciated, and presents

the ordinary symptoms of hectic fever. In many such cases, fortunately, more or less complete recovery takes place after a time. In many cases, on the other hand, the patient sinks slowly and at length dies, worn out and exhausted, or he dies with symptoms of septicæmia, or he is carried off by sudden intrapleural hemorrhage, or asphyxia. On the whole recovery was formerly more frequent when the empyema opened through the lung than when it discharged externally—a circumstance which seems to have depended in some degree on the much greater tendency there was in the latter case than in the former to decomposition of the purulent contents. The use of antiseptic methods, however, has now rendered the latter event by far the safer.

It often happens that the communication of an empyema with the bronchial tubes, or directly with the external atmosphere, permits of the entrance of air into the pleural sac, and that hence pneumothorax is established. The supervention of this condition may ordinarily be recognised by the presence of augmented resonance over the air-containing portion of the cavity, of the splashing sound caused by succussion, of cavernous resonance, and probably of distinct metallic tinkling.

In the foregoing account we have discussed the symptoms mainly of simple unilateral idiopathic pleurisy. The symptoms of the complicated disease are essentially the same, but they are interwoven with those of the complicating disorder, and are sometimes masked by them; and further, both pleuræ are occasionally implicated, with corresponding aggravation of symptoms. We may add that pleuritic patients, during the period of effusion, usually lie on or towards the affected side; and also that they much more frequently suffer from cough than might perhaps be gathered from the remarks we have made. The cough, however, is no necessary part of the disease, and is often due to the presence of associated pneumonia or bronchitis.

*Treatment.*—The treatment of ordinary cases of pleurisy is not usually a matter for anxiety. In mild cases of so-called ‘dry pleurisy’ the application of a mustard plaister or other counter-irritant, the binding of the chest with a broad flannel roller or the affected side with strapping to restrain its movements, and the use of opiates in small doses, will probably be sufficient.

In severer cases, in which there is manifest fever and increasing effusion, it is often beneficial to apply (according to circumstances) from half a dozen to a dozen leeches to the surface of the chest, to follow up their application by poultices or flannels wrung out of hot water, and then perhaps after a time by counter-irritants. In these cases, even more than in the former, opiates are of value, if only to alleviate pain and distress. Soda-water, or some other febrifuge medicine, may also be employed.

If the effusion still increase, and especially if the patient suffer from shortness of breath, the arrest of the effusion and the removal of the fluid which has already accumulated become the chief indications for treatment. For these purposes diuretics, diaphoretics, and purgatives have each been strongly advocated, and among drugs, mercury, antimony,

digitalis, and iodide of potassium. We believe that all such agents are practically useless for the purposes here indicated, and that, if we are to trust in drugs at all, they should be those which, by tending to improve the general health of the system, tend indirectly to promote healthy action at the seat of disease; we mean tonics, especially iron and quinine. Counter-irritants, and more particularly repeated small blisters, sometimes seem to aid absorption. The only other means at our disposal for the removal of fluid, and this is in many respects by far the best, is paracentesis. This operation was formerly greatly dreaded and seldom performed except in cases of empyema already pointing. It is in great measure due to Trousseau that, during of late years, paracentesis has come to be recognised as a safe and efficacious procedure in cases of excessive accumulation of simple serum. More recently, especially since the introduction of suction instruments, and through the able advocacy of Dr. Bowditch, the use of the operation has been still more widely extended. The objects to be attained by paracentesis are: first, the removal of pressure from the lung so as to permit of its redistension; second, the prevention of death from suffocation; and, third, the removal of purulent fluid. It is also generally believed, and perhaps correctly, that the discharge of a certain portion of fluid from a distended cavity promotes the absorption of the rest.

With the first of the above objects the fluid should be let out early, inasmuch as the longer the lung has been compressed and the more firmly it is bound down by adhesions the less likely is restoration to take place. With the second of these objects the pleura should be punctured either when the patient suffers from obvious difficulty of breathing, or when, even if dyspnoea seems absent, the cavity is greatly distended. The suspected presence of pus is always a legitimate ground for operation. In all these cases a fine trocar and cannula should be employed; the instrument should be plunged into the chest at a suitable point, always in some situation where the indications of fluid accumulation are best marked, but generally, as recommended by Dr. Bowditch, in an intercostal space, directly below the angle of the scapula and above the lower limit of the opposite healthy lung; and the fluid should be removed either by the aspirator, or by a tube guarded by a valvular fold of goldbeater's skin, so as to prevent the admission of air. The entrance of air, however, though an accident to be avoided as involving additional risk, often has no ill effect. It is not generally advisable to attempt the removal of the whole of the fluid at one time. If pus be present it may be taken away by periodical aspirations, or its free discharge may be maintained through a permanent opening. The best method of treatment is, we believe, to treat the case from first to last antiseptically, allowing the pus to escape freely through a large cannula or drainage-tube into antiseptic dressings, which should be renewed daily. In order to permit of a freer opening than can otherwise be obtained, it is sometimes desirable to resect a short length of one of the ribs. If the case assumes a chronic form, and especially if the discharge becomes fetid, it is important to wash out the cavity daily with

a weak solution of quinine, nitric acid, chlorinated soda, carbolic acid, or some other antiseptic.

The operation of paracentesis with a very fine trocar and cannula, if air be excluded, is perfectly harmless. And for this reason, as well as on account of the great importance of preventing permanent collapse of the lung, we strongly uphold the practice of the early and, if necessary, repeated removal of pleuritic fluid. Again, it is of little practical importance if in attempting paracentesis we wound the lung, kidney, or other neighbouring organs, and hence, although we recommend caution, we advocate early exploratory puncture when there is reason to suspect the presence of circumscribed accumulation of pus.

In the treatment of chronic pleurisy, or empyema, and during the whole period of convalescence, the importance of tonics, good diet, and change of air cannot be over-estimated.

## VI. CIRRHOSIS (*Chronic pneumonia. Fibroid phthisis*)

*Definition.*—A distinction is not unfrequently made between cirrhosis and chronic inflammation of the lungs. It is difficult, however, to appreciate in what the difference consists; and we prefer, therefore, to regard the two conditions as identical. We mean by these expressions induration of the lung, by the development of nucleated fibroid tissue, either around the bronchial tubes, or in the interlobular septa, or in the walls of the air-cells, or in all these situations at once, and the consequent gradual effacement of the air-cells.

*Causation.*—There is reason to believe that cirrhosis is an occasional result of ordinary acute pneumonia; it is far more frequently, however, a sequel of catarrhal or lobular-pneumonia, and of chronic pleurisy with effusion. A not uncommon cause is the habitual inhalation of solid particles, such as those of coal-dust, mill-stone grit, copper ore, flax-dust, and the like, by those whose occupations expose them to the danger of such inhalations. It is certain that it occasionally ensues on simple chronic bronchitis and on the retrogression of both grey and caseous tubercular deposits. The question how far, in some cases, it is to be regarded as the result of a constitutional taint, has been often raised. There is no doubt that we occasionally meet with a similar condition simultaneously involving several organs—more especially the lungs, liver, and kidneys—a fact which is certainly entitled to some weight on the affirmative side of the question. But, on the other hand, it must be remarked that hepatic cirrhosis is traceable, in the great majority of cases, to the influence of alcoholic irritation of the matrix of the liver, and that pulmonary cirrhosis (independent of tuberculosis) is usually limited exclusively to one or other lung—facts which are at least as weighty on the opposite side.

*Morbid anatomy.*—Cirrhosis of the lung consists essentially in the gradual invasion of the solid tissue of the organ by a nucleated fibroid

growth. This, on the one hand, surrounds and involves the bronchial tubes (especially the smaller ones) and the vessels which accompany them; on the other hand, invests the lung itself (which is then usually strongly adherent to the parietes) and separates its lobes from one another; and from both sides is prolonged into the interlobular septa, so as to divide the lung-tissue by bands of fibroid tissue of different degrees of density, thickness, and visibility, into a series of polygonal islets. With the further progress of the disease, the same kind of thickening takes place irregularly in the walls of the air-cells, so that before long the cut surface presents a coarse retiform arrangement of dense fibroid tissue; and this, gradually increasing, finally renders the whole organ, or portions of it, uniformly dense, hard, and airless. Although in cirrhosis there are usually both induration of the tissues around the bronchial tubes and dense adhesions between the opposed pleural surfaces, it often happens that the most obvious, if not the primary, change is that which pervades the ultimate tissue of the lungs. This is necessarily the most important.

Accompanying the interstitial growth of fibroid tissue, there is usually a more or less abundant deposit of black pigment in irregular patches. This is natural in the lungs of persons advanced in age; but in cirrhosis it is often, if not always, excessive. The pigment is seated in the thickened walls of the air-cells and especially in the connective tissue which surrounds the bronchial tubes and vessels, and separates the lobules from one another. It is always abundant also in the bronchial glands. It may often be found distinctly contained in the connective-tissue corpuscles, and taking the course of the lymphatic vessels. There is good reason to believe that it is to a large extent carbonaceous matter of extraneous origin, which has been inhaled into the lungs, has been absorbed by the mucous surface of the respiratory tract, and has then got deposited in the tissues and taken up by the lymphatics. The presence of pigment usually gives a peculiar mottled aspect to the sectional surface of the cirrhus lung; but, if in great abundance, it renders the tissues uniformly and intensely black.

The ultimate effect of cirrhosis of the lung, like that of the same condition in the liver, although it may perhaps under some circumstances cause temporary enlargement, is to produce gradual contraction and diminution of the organ. The progress of the disease is further always complicated with dilatation and other changes in the bronchial tubes, and not unfrequently with equivalent affections of the air-cells. The larger tubes are generally dilated, the fibroid and muscular bands which mark their mucous surface with longitudinal and transverse ridges are hypertrophied and produce a coarsely reticulated appearance, and the mucous membrane itself is probably congested and thickened. The chief changes, however, occur in connection with the smaller tubes, which in some cases are dilated into bulb-ended channels; sometimes terminate in round or sub-globular cystiform expansions, from the size of a cherry to that of a small pea; sometimes open (several of them in common) into cysts or

cavities of large size and irregular form ; sometimes are continued into recently-formed and progressing cavities, which, when small, may easily be recognised as originating in the ulcerative destruction of the walls of the smaller tubes and air-passages. The mode of origin of dilated tubes in this and other pathological conditions will be considered hereafter. It will be sufficient to say here, that, in many cases, so-called 'dilated tubes' are merely tubes in communication with cavities whose walls have undergone cicatrisation ; that there is (as might be supposed) a strong tendency for the adventitious fibroid growth of cirrhosis to undergo liquefaction under the influence of inflammatory processes commencing at the bronchial surface ; and that the formation not only of vomicæ, but probably also of many dilated tubes, are referrible to such liquefaction. Ordinarily in cirrhosis the air-cells undergo gradual obliteration, their diminishing cavities being sometimes filled with disintegrating epithelial and other cells ; but not unfrequently more or less emphysema is developed at the same time. When cirrhosis is limited to some comparatively small tract of lung, emphysema is common in the tissue which immediately bounds the indurated patch. Occasionally, also, the formation of a dense fibrous reticulum throughout the lung is associated to a greater or less extent with the breaking down of the thickened walls of dilated air-cells, so that the cut surface of the lung becomes not altogether unlike that of a coarse sponge. We believe that the condition last described may ensue on the retrogression of a crop of miliary tubercles.

Cirrhotic lungs present great variety of appearance and character ; at the same time it is easy to see that, however much they may differ from one another in the stage of the disease which they have reached, in the amount of pigment which is present in them, in the condition of their bronchial tubes, and in the tendency to the formation of vomicæ, they are all linked together by the community of their origin in simple fibroid overgrowth. The following are some of the varieties of cirrhosis which have been described and named:—*Red induration*—the name given to an early or slight condition of the disease, in which the lung is large, red, and fleshy, and, although denser than natural, and infiltrated to some extent with adventitious growth, is still generally crepitant: *Brown induration*—the name employed to designate a condition of lung in which the capillaries are dilated and thickened, and in which the colour of the organ has a yellowish-brown tint, and the fluid exuding on pressure is similarly coloured, in consequence of the presence in the tissues of the lung of the colouring matter of the blood in the form of pigment-granules ; brown induration is especially an accompaniment of heart-disease: *Grey induration*—the name sometimes applied to the condition of the lung in advanced cirrhosis, when the organ is extensively infiltrated with fibroid matter and presents in consequence a general greyish tint and a more or less translucent aspect: *Black induration*—which is sometimes used as the designation of that form of cirrhosis in which the cirrhotic tissue is largely infiltrated with black pigment, and of which the most striking examples are furnished by the lungs of persons working in mines or

otherwise exposed to the inhalation of soot or other carbonaceous matters.

The pulmonary affections which are so frequently the causes of death amongst those who are engaged in certain avocations, as, for example, among miners, colliers, flax-dressers, millstone-grinders, and the like, and which are commonly known as the phthisis of those who are thus respectively engaged, are mostly, as has already been indicated, of the nature of cirrhosis. They originate in the bronchitis which is caused and maintained by the constant inhalation of solid particles; of which many get deposited in the solid tissue of the lungs, and remain there permanently. The fibroid infiltration slowly supervenes. It appears from Dr. Greenhow's investigations that the nature of the dust inhaled does not exert any specific influence over the morbid changes which ensue. The nature of the imbedded particles can generally, however, be pretty readily recognised with the aid either of the microscope or of chemical reagents, or even, as in the case of iron rust, by the naked eye.

*Symptoms.*—The symptoms of cirrhosis of the lungs, apart from those of the numerous affections which complicate it, and from those of the morbid conditions out of which it may have arisen, scarcely admit of description or recognition. The disease is one the progress of which is exceedingly chronic, and may be prolonged for five, ten, or even fifteen years.

It is easy to see, if any large extent of lung-tissue be involved, that the patient must suffer from progressive breathlessness; that, from the obstruction which the indurated and contracted lung-tissue opposes to the pulmonic circulation, hypertrophy and dilatation of the right side of the heart must ensue, to be followed sooner or later by general anasarca; that there must gradually supervene impairment of nutrition, failure of the general powers of the body, weakness and emaciation; that the pulmonary changes must result in impairment of thoracic movement with retraction of the thoracic parietes, dulness on percussion, and either suppression of the respiratory sounds, tubular breathing, or (if there be secretion into the tubes) the various unnatural sounds which bronchial accumulation is competent to induce. Generally, moreover, there are present (at all events at some stage or other of the affection) more or less bronchitis with secretion, more or less dilatation of the tubes or air-cells, more or less breaking down of tissue with the formation of vomicæ, and more or less distinct inflammatory action; and the symptoms of these conditions must be added in order to have a true picture of the symptomatic phenomena of cirrhosis of the lungs.

Briefly, then, it may be stated that a patient with cirrhosis presents the following symptoms variously combined:—He has dyspnœa, especially on exertion, which gradually increases upon him, and is generally aggravated during the winter months, or by the occurrence of catarrh or pulmonary inflammation. Pallor and lividity of surface, with congestion of the nose, fingers, and toes, often supervene sooner or later. Cough is almost always present, and in some cases is very severe; it may, however,

be wholly absent, especially during warm weather. It may or may not be attended with expectoration; but expectoration is often profuse, especially when the cirrhosis is complicated with dilated tubes or vomicae, and generally muco-purulent or purulent. Under the same circumstances it is liable to be fetid, and, in the case of colliers and others, almost black from the presence of pigment-particles. Hæmoptysis is not unfrequent. In many cases the sputa are merely streaked with blood as in ordinary chronic bronchitis; in some cases, however, profuse hemorrhage occurs from time to time. This is due sometimes to perforation of blood-vessels in the course of destructive changes, sometimes to intense hyperæmia (probably of inflammatory origin) of the lining membrane of the dilated tubes. The auscultatory and percussive phenomena will be considerably modified according as dilated tubes or cavities are absent or present, and according as these are full or empty of fluid. The pulse may at first present little departure from the normal, but as the disease progresses it becomes rapid and weak, and sometimes irregular; and at the same time, as has been pointed out, general anasarca may ensue. Elevation of temperature and other febrile symptoms are very variable in their occurrence. Not unfrequently, at certain periods of the affection, there is a total absence of them. But much more commonly the patient presents the usual symptoms of hectic fever: elevation of temperature, which, however, is liable to fluctuations; perspirations; loss of appetite; sometimes vomiting and diarrhœa; and gradually increasing emaciation and debility. The local and general symptoms and history of cirrhosis not unfrequently closely resemble those of retraction of the lung after simple pleurisy, or those of chronic bronchitis with emphysema, or those of phthisis.

*Treatment.*—Our principal aims in the treatment of cirrhosis should be, by attention to hygiene and diet, to arrest the progress of the morbid process, to prevent the supervention of complications, and to maintain the bodily strength. For these purposes change of scene, removal to a mild but equable and bracing air in the summer, and to a warm southern climate in the winter, the avoidance of night air, exposure to sudden chills, over-fatigue and the like, the use of wholesome and abundant diet, with a moderate amount of stimulants, and the exhibition of quinine, iron, cod-liver oil, or other tonics, are of vital importance. When the cirrhosis is due to occupation the patient should give it up and follow some more healthy pursuit. But, in addition, symptoms, as they arise, will necessarily call for treatment: cough and expectoration may demand opiates and expectorants, hæmoptysis astringents, shortness of breath diffusible stimulants, diarrhœa medicines which check the alvine flux. It is needless, however, to pursue the list of possible complications and to indicate the various methods by which they may severally be relieved.

---

## VII. TUBERCLE

*(Laryngeal and Pulmonary Phthisis. Tubercular Pleurisy)*

*Causation.*—The etiology of tuberculosis is a subject of the highest interest. There are few affections in which the influence of hereditary taint is so strongly shown. It is well established that children of tubercular parents are pre-eminently liable to tubercular affections, and not only so but that, if one parent be tubercular, the children who most resemble that parent in conformation are usually most prone to be affected, and, further, that parents themselves seemingly healthy, or at all events free from tubercle, not unfrequently beget a family of children who die one after the other of pulmonary phthisis. In the case last referred to the tubercular tendency of the children may be due either to the transmission of a taint which is latent as regards the parent, or to the fact that one or other of the parents is scrofulous or syphilitic, or in some other way impaired in health. But tuberculosis does not occur only among those who inherit a tendency to it. Climate has certainly some influence in its production; for it is much more frequent in temperate climates than it is in those which are either very cold or very hot; and Dr. Buchanan's and Dr. Bowditch's researches seem to prove that in temperate climates it prevails far more extensively in low, damp situations than in such as are elevated and dry. There is no doubt that conditions which produce deterioration of the general health tend ultimately to induce tuberculosis; among which may be enumerated inadequate nourishment, excessive work with insufficient rest, and want of fresh air. Hygienic defects of this kind are especially injurious to the young. Other causes of tuberculosis are occupations which necessitate the inhalation of solid irritating particles (for there is no doubt that tuberculosis, as well as cirrhosis, and not unfrequently both in combination, are thus determined), and the cachexiæ which follow or attend upon enteric fever, measles, whooping-cough, syphilis, diabetes mellitus, and various other diseases. No age is free from liability to tuberculosis; it is extremely common in young children; but, putting these on one side, the age of greatest liability is from twenty to thirty or thirty-five. The influence of sex is uncertain.

Koch's discovery of the dependence of tubercle on parasitic organisms, which we have already discussed, and the truth of which is generally admitted, makes it certain that all the causes which have been considered in the foregoing paragraph, important though they are, are merely predisposing causes. It makes it certain, too, that tubercle is communicable, and probable therefore that its prevalence is directly or indirectly due to contagion taking effect on constitutions predisposed to suffer. The recognised tendency of tubercle, which has already been adverted to, to play havoc in families, is at least as explicable on the hypothesis of contagion as on that of inheritance. Indeed, careful inquiries, guided by our newer knowledge, are every day rendering it more and more certain that the disease is contagious, and that its spread is due to contagion.

*Morbid anatomy.*—1. *Laryngeal tubercle* manifests itself for the most part in the form of minute grey granulations, which may easily be overlooked, but which, nevertheless, present all the microscopical and other characteristics of grey tubercles. They are situated in the substance of the mucous membrane, and tend after a time to form small round shallow ulcers, which by their coalescence constitute sinuous but rarely extensive tracts of ulceration. Accompanying this ulceration there is usually more or less thickening and congestion of the surrounding tissues, chiefly in relation with the arytenoids, the aryteno-epiglottidean folds, and the epiglottis. Ulcers may occur in any situation, but affect more particularly the neighbourhood of the arytenoid cartilages, the epiglottis, and the vocal cords. They are apt to extend in depth, causing perichondritis and necrosis of cartilages, and leading, in some cases, to extensive destruction of the epiglottis or vocal cords. Attention may here be called to the view, now largely entertained, that lupus is a manifestation of tuberculosis, and, *a fortiori*, that lupus of the larynx is simply tuberculosis of that organ.

The trachea and bronchi are subject to the same pathological changes as the larynx; their mucous membrane gets congested and thickened, excoriations manifest themselves, with or without the pre-existence of miliary tubercles, and occasionally the cartilaginous rings become exposed and eroded, and even detached and expectorated.

2. *Pulmonary tubercle.*—Those who deny the identity between grey and yellow tubercle will, equally with those who maintain the opposite thesis, admit that the two varieties often co-exist in the same individual; and, on the other hand, those who believe in their identity will, equally with their opponents, acknowledge that cases of tuberculosis are not unfrequently met with which are apparently characterised by the exclusive presence of one or other form. It will be convenient therefore, while acknowledging their tendency to pass the one into the other, to describe them independently, as we not unfrequently meet with them in typical cases.

α Grey tubercles vary in bulk from mere points up to the size of a small pea, but do not usually exceed that of a pin's head; they are grey, somewhat hard, and slightly translucent; they are sometimes sparsely scattered, sometimes closely set, in some cases distributed with tolerable uniformity, in others forming scattered groups or clusters of various sizes. In the last case, those in the central part of a group coalesce, to a greater or less extent, and form tracts, individually as large as a marble or walnut. The development of grey tubercles is occasionally limited to one lung; more frequently it comprises both, and may then involve them equally or unequally. They are in some cases distributed throughout the whole organ, in some limited to certain regions, generally the apex; and for the most part, even when universally distributed, they are most numerous and advanced in the upper part of the lung. The growth of miliary tubercles is always, in a greater or less degree, associated with other morbid conditions of the lung; these are especially congestion and œdema

of the pulmonary tissue, consolidation of the intermediate tracts of lung, and bronchial catarrh mainly implicating the minuter tubules. The consolidation may be of the nature of ordinary pneumonia, with impaction of the air-cells with corpuscular elements; or of the nature of cirrhosis, with fibroid thickening of the walls of the air-cells and of the other connective tissues of the lung. A later change is the breaking-down of the consolidated bits of lung and the formation of vomicae. Such cavities usually commence at the apex, and may be limited to that part. They may vary from the size of a pea up to that of an orange or beyond, and may present every variety of form. They are usually surrounded with a greater or less thickness of indurated tissue, and often present abrupt, well-defined margins.

For the most part, miliary tubercles are developed with great rapidity, and tend to a rapidly fatal issue. Occasionally, however, their progress is arrested, and the patient recovers, but with permanent damage to the tissue of the lung. When this happens in respect of discrete tubercles the organ gets seamed throughout with minute patches of cicatricial tissue, the fibres of which have something of a stellate arrangement, and within the limits of which the lung-tissue presents, from the presence of concurrent emphysema, a coarsely spongy character; and occasionally in the centres of the scars minute fibroid knots or concretions may be recognised. When the affection becomes arrested after groups of tubercles have got consolidated by the intervention of inflammatory overgrowth, more or less extensive tracts of tissue, probably studded with cretaceous or caseous masses and black pigment, assume a cirrhotic character, and contract, while usually emphysema arises in their immediate neighbourhood. Further, when cavities have formed, they either shrink and become lined with a definite smooth membrane, continuous with that of the bronchial tubes, or possibly, in rare cases, get obliterated.

β Yellow tubercles in process of development present an opaque, yellowish-white, slightly granular character. They are dry and friable, furnishing no juice, but readily yielding, on being scraped or squeezed, a pulpy detritus. They are usually of larger size than grey tubercles, and present for the most part a well-defined outline and more or less irregular form. They evidently comprise groups of air-cells or lobules, and are hence polygonal when cut across; but, when divided in the direction of the bronchial tubes, are found to involve the minuter branches of these, and to be arranged upon them in a lobulated or foliaceous manner. In their early stage a cross-section will probably have the size of a split tare or pea; they soon, however, partly by individual growth, partly by coalescence, assume larger dimensions. Occasionally, as the result of such coalescence, large tracts of lung-tissue, possibly the whole of a lobe, become uniformly infiltrated—a condition to which the name of 'chronic pneumonic phthisis' has been given.

Yellow, like grey, tubercles, usually commence at the apex of a lung, sometimes at the apex of the lower lobe, and gradually spread thence downwards. They are usually, too, more advanced at the apex than else-

where. It must not be forgotten, however, that they may originate and attain their most advanced stage in any part of the lung. The tendency of yellow tubercles to undergo liquefaction is far more marked than that of grey tubercles ; so that, although a lung may become very largely involved without breaking down, in the great majority of cases softening takes place both early and extensively. In one case of rapid phthisis which came under our notice, destructive softening must have been almost <sup>ultrapro</sup> simultaneous with the development of the tubercles, for, though both lungs were thickly studded with cheesy masses, there was scarcely one of them which was not almost wholly converted into a flocculent-walled cavity. The lungs, indeed, were lighter than natural, and appeared at the first glance to have large air-containing bullæ thickly disseminated throughout their substance. The vomiceæ of this form of phthisis usually originate in the upper parts of the lungs and there attain their chief development. They commence with the liquefaction of those portions of the masses which immediately bound the bronchial passages and smaller tubules ; so that, in the first instance, though roundish when cut transversely, they possess a dendritic form when the incision takes the course of these channels. A cavity once commenced increases more or less rapidly in size, and ere long, by coalescence with neighbouring cavities, may assume gigantic proportions. It may even occupy the whole of a lobe. Large cavities are usually irregular or anfractuons in form, and often crossed by bands of condensed tissue, comprising vessels (mostly impervious) of considerable size. Cavities in process of formation present ragged parietes ; but when they have ceased (as they often do cease) to enlarge, their surfaces get smooth and even polished, and the tissues around them indurated. Yellow tubercle not unfrequently undergoes retrogressive changes. These consist in its gradual conversion, first into a mortary, and lastly into a calcareous, inert mass, encapsuled by a dense fibroid envelope. The contraction of cavities, the calcareous conversion of tubercular masses, and the induration of the tissues around, are always attended with diminution in the bulk of the affected portions of lung, and compensatory expansion or displacement of the neighbouring healthier tissues.

In both forms of tuberculosis it sometimes happens that gangrene takes place ; or that profuse hemorrhage occurs either from intensely congested surfaces or from perforation often preceded by aneurysmal dilatation of an artery ; or that the tubercular vomica, like any other abscess within the chest, opens into the pleura, or through the outer thoracic walls, or perforates the diaphragm. The aneurysms above referred to are usually about the size of a pea ; but they may be as large as a filbert or a chestnut.

3. *Pleural tubercle* differs in no important respect from tubercle of other serous membranes. It appears almost invariably in the form of minute greyish spots variously arranged, sometimes occupying the serous membrane itself, sometimes apparently imbedded in the substance of recently-formed false membranes. These bodies may be scattered over

the whole surface, or limited to certain spots; and are generally, even when widely spread, most thickly congregated in certain regions where it may be presumed they originated. They are often specially numerous between the lobes and upon the diaphragm. When very abundant they touch one another, or coalesce so as to form extensive tracts. When this takes place the opposed pleural surfaces are usually adherent, and the tubercular laminae appear to occupy the substance of the intervening false membrane. As the tubercles increase in size and run together they assume an opaque buff colour and become friable, resembling in look and consistence cheesy masses in the lungs. Pleural tubercle is, in the great majority of cases, associated with tubercle of other organs; occasionally, however, it is primary in the pleuræ, and may even be limited to one. It is commonly associated with tubercle of other serous membranes; and, as might be supposed, is usually coincident with some amount of similar disease in the lungs. It is nevertheless a fact that it is by no means a frequent complication of pulmonary phthisis, notwithstanding that pleuritic inflammation is an invariable attendant on that affection. Tubercle of the pleura is not necessarily accompanied by inflammation of that membrane; in most cases, however, sooner or later, and sometimes from the very commencement, inflammation takes place, and the usual phenomena of pleurisy then combine with those of tuberculosis; false membrane is formed, effusion takes place, perhaps suppuration ensues, and indeed any one or all of the various events which have been already fully considered under the head of pleurisy are apt to supervene.

It would be out of place here to enter at any length upon the associated morbid anatomy of tubercular affections of the respiratory organs, which, however, plays so important a part in the progress and symptoms of ordinary cases of pulmonary phthisis. It will be sufficient to draw attention to the fact that tubercles are rarely limited to these organs, and that their simultaneous development in other organs may induce consequences of much more urgent gravity than those referrible to the laryngeal, pulmonary, or pleural affection. Among the more important complications of pulmonary phthisis are inflammation of the lungs and pleuræ, tubercular meningitis, tubercular peritonitis, and tubercular ulceration of the intestine, to which may be added fatty and lardaceous degenerations of various organs.

*Symptoms and progress.*—So much attention has been devoted to the symptomatology of pulmonary phthisis, so much has been written on this subject, and so elaborate are the details with which we have been furnished that it seems at first sight an almost hopeless task to endeavour to compress our description of the symptoms of the disease within reasonable limits. When, however, we bear in mind that, in most of the elaborate accounts to which we refer, the symptoms of pulmonary phthisis are made to include the symptoms due to tuberculosis of all other organs, those referrible to the many complications which are apt to supervene in the course of phthisis, and besides these the symptoms of the various forms of ill-health which so often precede phthisis, it will be seen that

the symptomatology of the pulmonary affection has been overlaid with an abundance of matter which, however important, does not immediately concern us now. The following description will be limited almost exclusively to the symptoms which are referrible to the affections of the respiratory organs themselves.

In a large number of cases the invasion of pulmonary phthisis is remarkably insidious. A patient who has previously, it may be, enjoyed robust health slowly and without obvious cause becomes weak and thin, probably suffering at the same time from slight remittent febrile symptoms; or, possibly after exposure to the causes of catarrh, he becomes the subject of dry irritating cough which he cannot shake off, and ere long experiences loss of flesh and strength; or he suffers in the first instance from slight symptoms of laryngeal inflammation, which slowly increase in severity; or, without previous warning, he has a sudden and profuse attack of hæmoptysis, on the subsidence of which some of the various symptoms above considered supervene; or a patient, subsequent to an attack of fever or pneumonia, or in the course of some wasting disease, is attacked with cough, and the symptoms of phthisis gradually replace those of the primary malady. The frequent occurrence of gradual deterioration of health, without the presence of any specific symptoms of disease, prior to the obvious development of pulmonary phthisis, has induced many physicians to believe in the existence of a stage of phthisis antecedent to that of tubercular deposition—a belief based on utterly insufficient data.

But in whatever way phthisis first manifests itself, the symptoms of the fully-developed disease ere long become established. These consist mainly in cough, attended with muco-purulent expectoration, and occasional or frequent hæmoptysis; hectic fever, marked by periodical febrile exacerbations, profuse perspirations, especially at night time, rapid emaciation and loss of strength; and the local evidences, on percussion and auscultation, of progressive involvement and destruction of lung-tissue.

We proceed to discuss the various symptomatic phenomena of phthisis *seriatim*. In a certain number of cases the symptoms of which the patient first complains are referred to the larynx; and it may be that throughout the whole course of the affection the laryngeal symptoms continue chiefly distressing to him. These differ scarcely if at all from those of ordinary chronic laryngitis except in their obstinacy and progressive character, and in the gradual supervention of emaciation and loss of strength, and of indications of advancing pulmonary disease. In a still larger number of cases, and indeed in a very large proportion of the entire number of cases, of phthisis, laryngeal symptoms come on sooner or later in the course of the pulmonary disease. These are sometimes simply irritative or catarrhal, and subside; but more frequently they resemble in all respects, inclusive of their causation and progress, those of the earlier laryngeal affection. It is a question which can scarcely be said to be even now clearly decided, whether laryngeal

phthisis (as it is termed) ever actually precedes the pulmonary disease. The general belief is that it is always secondary, and there is no doubt that at post-mortem examinations laryngeal phthisis is never found unassociated with tubercles in the lungs. There is good reason, however, to suspect that tuberculosis sometimes begins in the throat or larynx, involving the lungs subsequently. The laryngoscopic characters of laryngeal phthisis have been described under the head of chronic laryngitis.

The presence of cough is one of the most constant and striking phenomena of phthisis. It generally begins early, and increases in frequency and severity with the progress of the disease. In the beginning it is usually short and hacking, and either dry or attended with scanty glairy expectoration. It is probably then due to slight bronchial irritation only, and the discharge consists mainly of bronchial mucus. With the advance of the disease and the breaking down of the pulmonary tissue, the sputa usually become increased in quantity, often very profuse, and at the same time opaque, yellowish or greenish, and purulent, often nummulated, sometimes fetid. The expectoration is not necessarily distinguishable from that of bronchitis. It is furnished partly by the inflamed bronchial tubes, partly by the tubercular vomice; and sometimes, by careful microscopic examination, pulmonary tissue may be detected in it. The characteristic bacilli can almost always be readily discovered in the sputum, even in the earliest stages of the disease; and in all cases of suspected phthisis should be looked for with sedulous care. The bacilli are generally abundant when the disease is active, but few, or even wanting, when it is quiescent or retrogressive. The cough has no special characteristics by which it may be distinguished from that of bronchitis, or (if the larynx be affected) from that of laryngitis. It presents, however, considerable differences in different cases; in some it is scarcely a matter of complaint from first to last; in some (especially chronic cases) it presents periodical variations, increasing, for example, in the winter or cold weather, subsiding in the summer time; but in the majority of cases it is a serious and increasing cause of distress.

Hæmoptysis is one of the commonest incidents of pulmonary phthisis. It occurs at some period or other in the course of the great majority of cases. Sometimes it is the first indication of the disease; more frequently it comes on at a later period. It may be only sufficient to tinge or streak the expectoration, or it may be limited to an occasional succession of sanguinolent sputa, or, again, it may be sudden and profuse—the patient bringing up in a very short time half-a-pint, a pint, or even a larger quantity of blood. It may be so profuse, indeed, at any stage of the disease that the patient is suddenly carried off either by choking or by syncope. But these sudden and profuse hemorrhages are usually among the earliest symptoms of phthisis.

Difficulty of breathing is a common but not necessary phenomenon. It may be severe if the larynx be largely affected, or if there be much accumulation in the bronchial tubes, or effusion into the pleuræ. In

most cases, however, the patient makes little or no complaint on this score; he no doubt readily loses wind on even slight exertion, and habitually, perhaps, the respirations are augmented in frequency; but when he is at rest his breathing does not usually trouble him.

The patient often suffers from stitch or burning or other kind of pain in the chest. This may occur on one or both sides, often at one apex, but is not limited to any one part. Pain is by no means always present; some patients never experience it; others suffer from it occasionally only; in some cases it is pretty constant and severe. It is usually augmented by movement of the chest, and especially by deep breathing or coughing. It is mostly due to pleuritic complication.

The physical signs of pulmonary phthisis are such as would naturally arise from progressive consolidation and contraction of the lung, the formation of cavities, the accumulation of secretion in them and in the bronchial tubes, and pleuritic inflammation and exudation. In considering the significance of the physical signs we must never forget that tuberculosis commences as a rule at one or both apices of the lungs, occasionally at the apices of the lower lobes, that excavation usually first takes place in the same situations, and that the morbid processes tend to travel downwards. Nevertheless, the earliest local indications of pulmonary tuberculosis, even if the tubercles as usual be most abundant at the apex, are occasionally discovered at the base of the lung, being due either to concurrent pleurisy or to progressive subacute pneumonia.

The presence of small discrete tubercles in the lungs, even if they be very numerous and close-set, does not necessarily affect the character of the percussion note or the sound which may be heard on auscultation. We can, therefore, readily understand that pulmonary tuberculosis may have made considerable progress before giving distinct local indications of its presence; and we must not too readily assume, because we hear nothing amiss, that, therefore, the patient is free from tubercle, or that he is in the so-called 'pre-tubercular stage.' Generally however, even if there be no dulness, there are bronchitic signs (rhonchus, crepitation, and the like), and these are probably most marked over the upper part of one or both lungs; or pleuritic friction, or jerky respiratory sounds, which have sometimes been attributed to the presence of circumscribed patches of pleuritic inflammation, may be audible in the same situation. When, however, tubercles have coalesced into masses, say from the size of a walnut upwards, and abut upon the surface, their presence materially affects the quality of the percussion note over the area to which they correspond. There is then dulness on percussion, the extent and completeness of which are determined by the extent and bulk of the consolidated tract. Dulness from tubercular disease is generally indicated by the facts: that it occurs mainly at the apex in front or behind; that it is rarely equal in these situations, and still more rarely equal in the corresponding points of both apices; and that it tends gradually to extend from above downwards, so as to involve more and more of the tissue of the lung. In association with dulness, there are usually increased sense

of resistance on percussion, increase of vocal fremitus, diminished movement during respiration, and flattening. The last condition is especially noticeable when it occurs beneath the clavicle. The auscultatory phenomena at this stage are mainly those which attend the second stage of pneumonia: tubular breathing, together with (if the tubes contain secretion) rhonchus, gurgling, crepitation, or occasional clicking or creaking sounds, bronchophony, and probably also pectoriloquy. It need scarcely be added that, if the consolidated patch be imbedded in the substance of crepitant lung, little or no indication of its presence may reach the ear. The phenomena which attend the presence of vomicæ are very various, and by no means always characteristic. The existence of one or several small cavities in the midst of consolidated tissue does not obviously modify the percussion note due to the consolidation. Large cavities, indeed, surrounded by a thick layer of condensed lung-tissue, generally yield almost absolute dullness. In other cases, however, the formation of a cavity in consolidated tissue is attended with the redevelopment of resonance, which may become almost normal, or may be high-pitched, or present the characters of the *bruit de pot fêlé*. On auscultation over cavities we may detect (if they contain fluid) large crepitation and gurgling—sounds which may also be heard over the larger bronchial tubes when imbedded in condensed lung-tissue; or (if they be empty) some modification of tubular breathing. Occasionally (and this may be the case in respect of cavities no larger than a walnut) we may hear distinct cavernous sounds. Metallic tinkling is seldom audible over tubercular cavities. In some cases no sounds whatever are produced within a cavity, and all that one hears are normal or abnormal respiratory sounds transmitted from the parts beyond. Both bronchophony and pectoriloquy may usually be recognised; pectoriloquy, however, is on the whole more marked here than over solid lung, bronchophony perhaps less marked.

In delicate patients in whom no obvious consolidation can be recognised, the persistent presence, at one or other apex, of harsh and prolonged expiratory murmur, of a few clicking sounds, of rhonchus, of crepitation, or of jerky respiration, is ground for the gravest suspicion. By some physicians, moreover, a systolic murmur over the pulmonary artery and its main branches, or in the course of the subclavian artery within the chest, is equally regarded as an indication of the presence of tubercular consolidation—the belief being that the murmurs are produced by the pressure of consolidated tissue upon the vessels in question.

The state and action of the circulatory organs are for the most part such as we meet with in all chronic diseases attended with progressive debility and emaciation. In the earlier stages of phthisis the pulse is usually increased in frequency and hardness; with the advance of the disease its frequency becomes augmented, but there is diminution of fulness and force. With increasing enfeeblement of the circulation it is not uncommon for some degree of anasarca to supervene, especially if the enfeeblement of the left side of the heart be associated, as it

occasionally is, with hypertrophy and dilatation of the right side. As a rule, however, the heart undergoes general atrophy. In many cases the anasarca is limited to the lower extremities, and is then often due immediately to thrombosis of the iliac veins. It is doubtless owing to the same enfeeblement of the circulation that various parts, and more especially the nose, ears, fingers, and toes, frequently get congested, livid, and tumid. A clubbed condition of the fingers and toes (although by no means confined to phthisis) is, as is well known, of common occurrence in the chronic form of the disease. Each ungual phalanx becomes swollen and bulbous, and at the same time more or less congested; and in consequence of the grape-like form which it assumes, the nail, which occupies the upper half only, becomes bent over the summit, forming a kind of sloping roof.

The symptoms referrible to the stomach and bowels are generally of considerable importance. The tongue may be clean throughout the greater part of the patient's illness; it is often morbidly red, however, and often furred, and towards the fatal termination is apt to get dry, glazed, and fissured or aphthous. Thirst is usual. The condition of the appetite presents great variety. In some cases it is good, and possibly voracious; in others it is capricious; while in others again there is complete anorexia, and probably great irritability of stomach, with gastrodynia, nausea, and sickness. The latter conditions depend in some cases on catarrhal inflammation of the mucous membrane of the stomach, and are often associated with thinning and dilatation of that organ. Phthisical patients are exceedingly liable to suffer from diarrhœa, which is often very obstinate and profuse, and often assumes a dysenteric character. Persistent diarrhœa, indeed, may be the most serious of all the morbid conditions from which the patient suffers. It is due, in the great majority of cases, to coincident ulceration of the bowels—a lesion which complicates fully one-half of the cases of pulmonary phthisis, and which may outrun, if it do not precede, the pulmonary disease. Diarrhœa may result, however, like the dyspeptic symptoms, from mere catarrh, or some other form of irritation of the mucous membrane. It is a well-recognised fact that tubercular patients are apt to suffer from fistula in ano. The presence of a fatty liver is seldom indicated by symptoms, but may occasionally be recognised by the increased bulk which the organ attains.

The nervous system does not usually present any very characteristic morbid phenomena. The patient may be irritable, or, on the other hand, apathetic; he is sometimes desponding, but much more frequently hopeful, buoying himself up even to the last with the prospect of eventual recovery.

Hectic fever and gradual emaciation are by far the most important and striking of the general phenomena of phthisis. They commence in most cases long before the actual proofs of the growth of tubercles exist, and they continue, as a rule, throughout the whole duration of the disease. It is important, however, to observe that phthisical patients often undergo temporary improvement, that under judicious management they often

gain flesh and strength, sometimes never lose flesh, and that they not unfrequently remain free from fever for weeks together—sometimes, indeed, have scarcely any febrile symptoms during the whole course of their illness.

The hectic of phthisis is almost typical in the distinctness of the daily remissions and exacerbations which attend it. There is usually some elevation of temperature after food, especially after hearty meals, but the maximum occurs mostly in the afternoon or evening. The minimum temperature in the day may be normal, or even below the normal; the maximum may reach anything from  $101^{\circ}$  to  $104^{\circ}$  or even  $105^{\circ}$ . In most cases, however, the lowest temperature is still considerably higher than natural, and the range less wide than the above figures might seem to indicate. Not uncommonly the temperature falls considerably as the fatal end approaches. The patient usually suffers during the periods of exacerbation from heat in the palms and soles, and flushing of the cheeks, which is for the most part vivid and circumscribed, and has received the name of the 'hectic flush.' Perspiration is a common and distressing symptom. The patient complains little of this while he is awake, but when he is asleep sweats are apt to break out profusely all over him, rendering his surface damp and sodden, and his linen and coverings in some cases so wet that the moisture may be wrung out of them. These perspirations are sometimes absent, or they may intermit, or be so slight as to be of little significance.

The emaciation of phthisis is intimately related to the presence of hectic fever, both being the consequence mainly of the rapid disintegration of the corporeal tissues. All parts of the body, doubtless, waste; some, however (especially the brain and nervous system), less than others. The heart dwindles; the bones and muscles become atrophic; but the most obvious change is in the fat, which gradually and for the most part almost entirely disappears. The limbs and trunk consequently shrink, and their surface falls into wrinkles; the skin of the face and forehead becomes closely applied to the subjacent bones and muscles, so that the cheek-bones, and especially the zygomatic arches, acquire remarkable prominence, and the movements of the muscles get painfully visible. The skin itself in many cases grows thin and brittle, the nails dry and inclined to split, and the hair thin and scanty. In some cases, however, no such changes in the cutaneous organs take place, and indeed the hair occasionally presents extraordinary luxuriance. The extreme emaciation favours the development of bed-sores on the buttocks and elsewhere.

In a large number of cases of phthisis, the presence of complications already adverted to (more especially cerebral, peritoneal, and renal tuberculosis, and degenerative affections of the liver and kidneys) adds other symptoms to those which have been enumerated, and materially modifies the progress of the disease.

Several varieties of phthisis, which do not necessarily correspond to the several varieties recognised by the pathologist, are described by those

who look at the disease from the clinical point of view. They may be ranged under the heads of acute and chronic phthisis.

Most cases belong to the chronic category. They commence in one or other of the ways already indicated, and the general symptoms and local changes which have been above discussed become gradually established. In many cases the disease progresses uniformly, no amendment whatever takes place, and the patient sinks probably in from six to twelve months from the first manifestation of symptoms. In some cases the duration of the disease is greatly extended; the patient suffers from the ordinary symptoms of phthisis, or it may be from those of a simple bronchial attack, and then appears to recover more or less completely; but after a while the symptoms recur, and again amendment follows; and again and again, it may be, these alternations of illness and comparatively good health take place, until at length the symptoms of the disease become continuous, and the patient gradually sinks. In such cases the tubercular process probably takes place in successive crops; and it is in them that post mortem we find intermingled, extensive tracts of indurated and contracted lung-tissue, encapsuled mortary or cretaceous masses, cavities with cicatrised parietes, and emphysemata. Tuberculosis dependent on the constant inhalation of irritating matters for the most part takes a similar course. Indeed, when phthisis becomes thus chronic, it approaches, both in its morbid anatomy and in its symptoms, the lung-affections already discussed under the name of cirrhosis. In some cases the progress of the disease is permanently arrested; and then, in proportion to the extent to which the lung-tissue may have undergone disorganisation, is the restoration to health complete or incomplete.

In acute phthisis the patient may die in the course of a few weeks, and generally dies within three months. Two varieties of acute phthisis may be distinguished:—first, that in which the tubercles are from the first mainly, if not entirely, yellow, and in which there is very rapid breaking down of lung-tissue; and, second, that in which the tubercles are milary. The first variety resembles the ordinary chronic form of phthisis in its symptoms, excepting only their intensity and the extreme rapidity of their development. It usually begins suddenly with high fever and rigors, and pulmonary symptoms which have a close resemblance to those of ordinary pneumonia. It is, in fact, with this disease that it is especially liable to be confounded. The second variety also comes on with fever and rigors, and possibly, but not necessarily, some bronchial irritation and cough. The symptoms indeed, both at the onset and for some time (sometimes throughout the whole course of the disease), have a marked resemblance to those of enteric fever with pulmonary complication. The state of the pulse, tongue, and cerebral functions may be identical in the two affections: in both the bowels may be constipated or loose; in both there may be abdominal tenderness and tumefaction; in both the febrile temperature shows marked remissions; in both dyspnoea is apt to supervene, and the face to become ghastly or livid. The motions, however,

are rarely peasoup-like in the tubercular disease ; the pain in the abdomen is less constant, and, if present, is due to peritoneal tuberculosis, and therefore less likely to be localised in the caecal region ; the temperature does not present the uniform variations characteristic of enteric fever, and there is an absence of the typical typhoid rash. The disease may prove fatal without the development of dulness, and without the evidence of the formation of cavities. Usually, however, as the disease advances, the lungs undergo consolidation, commencing at the apices and extending downwards.

Death in phthisis is due in most cases to asthenia, generally of slow development, but sometimes rapid, and immediately referrible either to extremely profuse alvine flux, or to sudden and copious hæmoptysis. In some cases it may be referred in part or wholly to asphyxia. Such may be the cause of death in phthisis associated with laryngeal disease, or much secretion into the bronchial tubes, or when there is sudden effusion of blood into the air-passages.

There are no symptoms by which tubercular pleurisy can be distinguished from the simple inflammatory affection, apart from its intractable character and the concurrent or consecutive appearance of tubercles in other organs.

*Treatment.*—It is of the first importance in the treatment of the early stages of phthisis, and indeed in the treatment of all persons in whom a tendency to phthisis appears to exist, to adopt every available measure to promote the general health, to take every precaution against the infraction of hygienic laws. It is obvious, therefore, that many of the details of treatment are such as, under the circumstances, common-sense would dictate. We may, however, enumerate a few of the matters here referred to. The diet should be wholesome and nutritious, and fairly distributed among the recognised meals ; the patient should keep good hours, refrain from all overwork, whether mental or bodily, clothe himself warmly, and live in temperate, well-ventilated, but not draughty rooms. At the same time he should not refrain from amusement ; nor need he abstain from business or other occupations if they be not too absorbing, or of an unhealthy nature ; and he should (if the weather be suitable) take an ample amount of gentle outdoor exercise.

Good milk and eggs are especially valuable as articles of food for phthisical patients ; but in their dietary frequent changes and considerable latitude are often necessary ; and, further, alcoholic stimulants, though probably not essential, are often apparently very beneficial. For the purpose of bodily warmth flannel should be worn next the skin.

The question of change of air is at this time one of the most momentous that can be raised. Shall the patient leave his home, and, if so, whither shall he go, and when ? The great desideratum for phthisical patients appears to be a climate of moderate temperature, liable to slight variations only, and neither largely saturated with moisture nor of extreme dryness. It is exceedingly rare, however, for any climate to possess such uniformity of qualities during the whole year, and it is generally

necessary, therefore, in order to secure the full benefit of climate, to change the locality according to the season. Hence it will be understood that, while most fairly healthy inland or seaside places in this country may suit phthisical patients reasonably well during the warmer months of the year, it will probably be necessary to select some sheltered spot upon the South Coast for winter residence; that while the bracing atmosphere of Scotland or Sweden, or of the higher regions of Switzerland and Tyrol may be exceedingly suitable during the summer, the South of Europe, or the North of Africa, or the Azores or Canary Islands, may be especially beneficial during the winter. Low-lying, moist, imperfectly drained localities are specially detrimental, and should be carefully avoided. On the other hand, the advantages of the pure, crisp air of alpine regions is now generally recognised, and there can be no doubt that for many patients a residence in such regions, even during the winter months, is beneficial. There is, however, large choice, and it may be added that a sea voyage is often of great service. But, notwithstanding the enormous benefits that not unfrequently accrue from judicious change of climate, or the permanent removal to a locality which experience may have shown to be especially suitable for the patient, it must not be forgotten that such changes often entirely fail to do good, and that they are altogether uncalled for and useless when the disease is acute in its progress, or far advanced.

In addition to the above hygienic measures, and to the same end, it is generally advisable to have recourse to medicines. No drug with which we are acquainted has any specific influence over the tubercular process. But there are some drugs which, by improving the general health, tend indirectly to check its progress. Of these iron, quinine, and other vegetable bitters are amongst the most valuable. But there is one article—drug or food—namely, cod-liver oil, which during the last forty years has acquired a special reputation. There is little doubt on the part of practical physicians, none on the part of the public, of the great value of this in the treatment of phthisical and scrofulous patients. It may be given in doses of from a drachm to an ounce three times a day. It is generally advisable, however, to begin with a small dose in order to avoid the production of nausea, and prevent the patient from taking a dislike to it. It is now largely believed that the virtues of cod-liver oil depend simply upon the fatty matter of which it mainly consists; and hence it has been assumed that other fats might prove equally beneficial. The use of cream, neat's-foot oil, olive oil, and other vegetable and animal fats, and of glycerine, has consequently been recommended. A great and sometimes insuperable bar to the administration of food, and to the use of the remedies which have been enumerated, is the irritability of stomach which is so often associated with phthisis. Hence, in a large number of phthisical cases, the condition of the stomach claims our first attention. It is impossible to lay down special rules for their treatment; we must have recourse to some of the various measures which are serviceable in the more ordinary forms of dyspepsia, and above all, perhaps, we must

adapt the tonic or combination of tonics we employ to the condition of the patient's stomach.

A great part of the treatment of phthisis usually consists in treating symptoms as they arise. None of these symptoms probably is special to phthisis, and all may be treated in accordance with the rules which guide us under other circumstances. Local pains must be obviated by counter-irritation; laryngeal affections by counter-irritation, applications to the interior of the larynx, and inhalation; cough and expectoration, according to circumstances, by expectorants (ipecacuanha, and the like), astringents, or sedatives; diarrhœa by lead or tannic acid, or other of the numerous remedies which check intestinal secretion or assuage peristalsis. For the above and many other purposes, no one remedy is so generally useful as opium in its various preparations; it relieves pain and discomfort, diminishes cough and expectoration, and restrains the action of the bowels. The nocturnal perspirations often defy treatment; to check them it is desirable that the patient should not be heavily laden with bed-clothes, and that his room should be cool. The surface of the body too may be sponged before he goes to sleep. Belladonna, the mineral acids, oxide of zinc, and various other astringent remedies have been largely employed for the same purpose. Also food or wine given in the night shortly before the hour at which perspiration usually occurs seems occasionally to prevent it. With the object of arresting hæmoptysis, the use of ice and ice-cold drinks and foods, and the administration of astringent drugs, especially digitalis, lead, ergot, and gallic acid, are usually advocated. Large cavities, whose walls secrete abundantly, may occasionally, like circumscribed empyemas, be tapped with benefit.

It may be well to point out that, while circumstances occasionally arise to render the local abstraction of blood or the use of emetics or purgatives necessary, all depressing treatment is, as a rule, to be eschewed; that during the later period of the disease stimulants are often of extreme value; and that in cases of acute phthisis tonics, cod-liver oil, and change of air are usually equally inefficacious.

In conclusion, it must not be forgotten that Koch's researches on the ætiology of tubercle, which remove all reasonable doubt as to the contagiousness of phthisis, make it imperative on us to adopt all precautions against its spread, just as we do against the spread of the recognised dangerous infectious fevers. With this object not only should the sputa and other discharges liable to contain bacilli be disinfected or destroyed, but free intercourse between the sick and the healthy should be prevented as far as possible; and the rooms which the sick have occupied, and all articles in them, should be disinfected after use. The importance of such measures is especially great when phthisis makes its appearance in a family of young and susceptible persons, and the more so that sympathy and love for the sufferer tend to oppose the adoption of the precautions which are so important. It need scarcely be said that in such cases the patient should associate as little as possible with the brothers and sisters,

and should at any rate occupy a separate sleeping-room. If the interests of the healthy are alone to be considered, the separation should be complete.

### VIII. SYPHILIS<sup>1</sup>

*Morbid anatomy.*—1. *Larynx, trachea, and bronchial tubes.*—The mucous membrane of the larynx may become the seat of erythematous inflammation during that early period of syphilis in which the skin is similarly involved; and there may even be some excoriation of surface. At a later period, usually, mucous tubercles arise on the laryngeal surface, in common with that of the neighbouring pharynx. These commence as small gland-like elevations, which gradually extend and coalesce. They may appear at any part—on the epiglottis and vocal cords, but especially (according to Morell Mackenzie) on the inter-arytenoidean fold. They furnish a pretty abundant secretion, and tend to ulcerate—the ulceration extending in surface and depth, and leading, according to its situation, to destruction of the epiglottis or vocal cords, and not unfrequently to caries or<sup>r</sup> necrosis of the thyroid, cricoid, or arytenoid cartilages. During the so-called ‘tertiary period’ of syphilis, gummata appear beneath the mucous membrane, involving not merely the connective tissue but the muscles and other parts. In this way tumours of considerable bulk may be developed. These, like other gummata, tend to undergo rapid degenerative changes, and to end in the formation of deep unhealthy-looking ulcers. All syphilitic ulcers, when they extend deeply, are apt to involve the destruction of the cartilages, to lead to communication between the larynx and the œsophagus, and to lay open arteries sufficiently large to allow of fatal hemorrhage; and all, when they heal, leave dense reticulated cicatrices which not unfrequently produce serious contraction of the channel of the larynx. Syphilitic disease of the perichondrium may arise independently of ulceration or gummata, and lead to necrosis of the cartilages.

Similar affections to those just described may involve not only the trachea, but probably also the bronchial tubes. There is reason to believe that a form of syphilitic erythema may attack the bronchia as well as the trachea; and there is no doubt that syphilitic thickening of the mucous membrane and gummata of their deeper tissues are not altogether unfrequent in both situations. These affections also in their further progress lead to ulceration, destruction of cartilages, and cicatrization with contraction.

2. *Lungs.*—Syphilitic affections of the lungs are imperfectly understood. It is well known that syphilitic patients frequently fall victims to pulmonary phthisis, and the question has naturally presented itself whether the apparently tubercular formations in such cases may not be

<sup>1</sup> Syphilitic affections of the larynx and trachea have already been briefly considered in connection with chronic laryngitis.

really syphilitic. The question is not altogether easy of solution ; for while, on the one hand, we have no reason to believe that the presence of syphilis excludes that of tuberculosis ; on the other, we know that there is a close anatomical resemblance between syphilitic gummata and tubercles. There is no reasonable doubt, however, that the lungs occasionally present specific syphilitic lesions ; and that these commence with proliferation of the connective tissue of the organ, beneath the pleura, around the bronchial tubes and vessels, and in the interlobular septa, and terminate in the formation of ill-defined patches, in which the tissue is indurated, greyish, and contracted, and converted mainly into fibroid or cicatricial tissue, studded in some instances with caseous or calcareous nodules. The caseous nodules in the lung as elsewhere, though having a close resemblance to tubercles, are usually much less friable than these latter are ; the fibroid growth differs little, if at all, from that observed in ordinary cases of chronic or fibroid pneumonia ; but Drs. Greenfield and Goodhart<sup>1</sup> point out that in its early stage it is characterised by great vascularity. The above growths are usually associated with syphilitic affection of the bronchial tubes, they commonly abut on the surface of the lung, and the pleura covering them is apt to be thickened, seamed, and puckered. Virchow and others have described a kind of *white hepatisation* of the lungs of stillborn syphilitic children, the origin of which they refer to the syphilitic poison. The lung, or lungs, or large portions of them, are dense, yellowish-white, opaque, tough but retaining the impress of the finger. They have been observed in association with syphilitic pemphigus.

*Symptoms and progress.*—The symptoms of syphilitic disease of the larynx are essentially the same as those which have been ascribed to chronic laryngitis. The affection, however, especially if it be connected with the formation of mucous tubercles or of gummata, is extremely intractable, rarely terminating in complete restoration to health, and frequently leading to one or other of the graver lesions which have been enumerated. Syphilitic affections of the bronchial tubes equally simulate in their symptoms ordinary chronic bronchitis.

With the few clinical facts which we possess in reference to the subject, it would be a mere exercise of ingenuity to describe at length the symptoms which may be produced by pulmonary syphilis. It is sufficient to say : that the diseases with which it is most likely to be confounded are chronic bronchitis, chronic phthisis, cirrhosis, and the consequences of these affections ; that profuse hæmoptysis seems to be not uncommon ; and that the presence of a history of syphilis, and of the superficial indications of syphilis, of course furnishes an important element of diagnosis.

*Treatment.*—In treating syphilitic affections of the larynx, trachea, bronchial tubes and lungs, our main trust must be placed in ordinary anti-venereal remedies.

<sup>1</sup> 'Transactions of the Pathological Society of London,' vol. xxviii.

## IX. TUMOURS

A. *Tumours of Larynx*

*Morbid anatomy.*—The larynx is a frequent seat of adventitious growths. 1. Of *non-malignant* kinds the most common are fibromata. These may be simple tumours of a rounded or lobulated form, pedunculated, and varying, it may be, from the size of a filbert downwards; or they may be similar bodies associated with overgrowth of the mucous glands and the formation of cysts; or they may have a papillomatous or warty character. The last are far more common than the others. They rarely exceed the size of a horse-bean, and are not generally larger than a split-pea. They are, however, often multiple, and tend to spread over a considerable surface. Fibromata usually originate on or near the vocal cords, but are not limited to these localities. They are not unfrequent in children, but may appear at any age. 2. *Malignant* tumours are mostly epitheliomatous, but are sometimes sarcomatous or cancerous. The first of these commences either in the pharynx, involving the laryngeal tissues secondarily, or at some part or other of the surface of the larynx. The others originate among the deeper textures.

*Symptoms and progress.*—The symptoms to which simple polypi give rise creep on gradually, and probably consist at first in a little hoarseness, or loss of voice, with a tendency to clear the throat or to cough, and an occasional feeling as if there were some foreign body in the larynx. The phenomena, indeed, are undistinguishable at this time, except by means of the laryngoscope, from those of ordinary subacute laryngitis. At a later period their presence gives rise to aphonia, to more or less serious impediment to respiration, and finally to death from asphyxia. If the laryngeal tumour be pedunculated, the symptoms are apt to vary with its change of position, and especially the patient is sometimes liable to sudden attacks of choking (which may at any time prove fatal) owing to the impaction of the tumour in the rima glottidis. If it be large as well as pedunculated, it may sometimes be seen at the back of the throat without instrumental aid.

Malignant growths commence, like other growths, insidiously, making little show and producing few symptoms; and for awhile there may be nothing to cause grave suspicion. Gradually, however, they enlarge, form tumours which from their mere bulk interfere with respiration and other necessary acts, undergo destructive changes which give rise to copious discharges, involve the epiglottis, aryteno-epiglottidean folds, vocal cords, and other parts, and perhaps cause sinuses to form in the neck or openings between the larynx and œsophagus. Sometimes they lead to the erosion of arteries and sudden arterial hemorrhage. Carcinoma, commencing in the glandular or other tissues external to the larynx, occasionally involves that organ in the course of its extension; and sometimes, indeed, when the external tissues are largely infiltrated, the larynx gets imbedded in them and fixed. At first it is difficult, if not

impossible, to recognise the presence of carcinoma, even on laryngoscopic examination. The rapidity of the growth of the tumour, however, the progressive character and extent of the ulceration which attends it, the fetor of its discharge, and the gradual involvement of the concatenate glands, all tend finally to render the diagnosis clear.

*Treatment.*—Previous to the use of the laryngoscope, even simple tumours of the larynx were to a large extent fatal. They were then rarely recognised; and, being allowed to grow without let or hindrance, ended by asphyxiating the patient. With the laryngoscope, however, their recognition is, even if they be small, comparatively easy, and their cure for the most part a matter of little difficulty. If they be small or pedunculated, they may be removed by means of curved forceps of special construction: for those growing at the back or front forceps opening laterally; for such as grow at the side forceps opening anteriorly and posteriorly. In some cases they may be removed by knife-edged forceps or scissors. It is inexpedient to employ much force, for the mere crushing which follows the attempt at removal (especially if it be repeated) often leads to atrophy of the growth. Occasionally, when the irritability of the larynx is extreme, or the patient is suffering from great dyspnoea, or under other special circumstances, it becomes essential to perform tracheotomy previously to operating on the larynx itself. Astringent and other applications to the mucous membrane are of little or no use. The treatment of malignant affections of the larynx can never of course be curative; occasionally, however, some relief may be afforded by the various local measures which are serviceable in chronic laryngitis. In any case, tracheotomy is sometimes necessary to prevent death from suffocation.

### B. *Tumours of Lungs and Pleuræ*

*Morbid anatomy.*—*Non-malignant* growths of the lungs and pleuræ are of little pathological and still less clinical interest; *malignant growths*, on the other hand, are highly interesting and important. There is probably no form of malignant disease which has not been discovered at one time or other in these organs; and probably each form has (apart from its microscopical characters) special peculiarities as to distribution, progress, and symptomatology. In the present state of our knowledge, however, it would be an excessive and needless refinement to discuss them separately.

Malignant disease either originates within the lungs, or extends to them by continuity from the mediastinum or other adjoining parts, or is secondary to similar disease of some distant organ. In the first case it usually constitutes a solitary mass; in the second it often runs along the bronchial tubes; in the third it is for the most part multiple. These several features are, however, by no means absolutely distinctive. The morbid process begins in the connective tissue, and therefore either in the walls of the air-cells, in the interlobular tissue, in the course of the bronchial tubes and their attendant vessels, or in the thickness of the pleural membrane and sub-pleural tissue.

When the growth extends along the bronchial tubes the connective

tissue which surrounds them becomes infiltrated and thickened, and the tubes and vessels set, as it were, in the solidified tissue. Moreover, the walls of the bronchial tubes themselves ere long get involved: in some instances those parts only which are external to the cartilages, in some those only which are internal to them, but for the most part their whole thickness. The affection of the mucous surface manifests itself by the appearance of small, disc-like elevations, which are at first scattered, but soon run together, forming a uniformly elevated slightly translucent tract, from which all the normal longitudinal and other markings are more or less completely effaced. Although the disease commences at the root of the lung, and is for the most part further advanced there than it is elsewhere, its distribution is not always continuous; but tracts of healthy and diseased tissues and healthy and diseased tubes frequently alternate one with another.

Malignant disease, attacking the pleura and subpleural tissue, frequently appears in the form of small greyish lenticular thickenings, which have been likened to drops of tallow or wax. They are sometimes so little prominent and thin as to be scarcely visible; sometimes they form distinct papular or tubercular elevations. In its further progress, the former variety tends gradually to form tolerably uniform tracts of considerable extent; the latter variety tends to the production of pedunculated outgrowths, which may hang singly or in clusters into the pleural cavity, and may vary from the size (say) of a pin's head up to that of a bunch of currants, an orange, or a cocoa-nut.

Whenever the morbid growth commences in the tissues which surround the bronchial tubes, or in the subserous tissue, there is a disposition for it to extend into the substance of the lung along the interlobular septa, and consequently for the affected lung to assume some of the characters which are so common in cirrhosis, and to some extent characteristic of it.

In most cases malignant disease of the lungs shows itself in the form of one or more distinct tumours. These, while yet of moderate size, have a rounded form, and if they abut on the surface often assume there the central depression and the tumid margin which characterise hepatic cancer. When such tumours increase in size, as they usually do, with some rapidity, they become irregular in form; and from the fact that they are then apt to get blended with the results of inflammation and pulmonary hemorrhage, their limits are often difficult to define. In the progress of extension of malignant disease from the bronchial tubes or pleura, it is common for distinct tumours to form here and there in the lungs. Malignant growths of the lungs, like those of all other organs, tend rapidly to undergo degenerative changes, and hence soon break down and form vomicae. Not unfrequently sloughing takes place in them, and masses of the morbid tissue may become detached.

*Symptoms and progress.*—The symptoms to which malignant growths of the intrathoracic respiratory organs give rise are, for many reasons, exceedingly variable. If the disease affect principally the serous membrane,

the symptoms have a resemblance to those of ordinary pleurisy; if the bronchial tubes be its main seat, the symptoms naturally approximate to those of bronchitis; if tumours form, they may afford the physical indications, if they be sufficiently large, of consolidation, and if they break down, of vomicae, and may be attended with purulent or bloody, probably fetid, expectoration. Still it must not be forgotten that malignant growths, in the early period of their formation, not unfrequently give no sign whatever of their presence, and that the patient may seem in fair, if not in his ordinary robust, health, up to the sudden supervention of some inflammatory complication or of hæmoptysis.

Malignant disease affecting the pleura generally ere long excites inflammatory action, and the formation of false membrane, with temporary stitch and friction-sound audible during respiration, and is probably always, sooner or later, attended with effusion of fluid. This effusion usually gives rise to no symptoms beyond those due to the compression which it exerts. It tends so to accumulate as to distend the pleura, and is persistent, always returning and generally with rapidity after paracentesis. It is mostly mere ordinary dropsical serum. In some cases, however, it is distinctly inflammatory; and it may be purulent. But it not unfrequently happens, especially if the adjoining lung-tissue be implicated, that it is mixed with blood, or that it is stained with altered blood-pigment, being green, yellow, or brown, or that it is glairy like the fluid from an ovarian cyst.

When the bronchial tubes and the parts surrounding them are the chief seats of disease, the symptoms, as before indicated, are mainly bronchial. Assuming that the patient has never previously suffered from bronchitis, the symptoms are characterised by their insidious approach; but when so far developed as to be a source of distinct discomfort they differ little if at all from those of progressive subacute or chronic bronchitis in some of its phases. There is probably at first some difficulty of breathing, increased by exertion, with little or no distinct local evidence of lung-disease, or at most a little localised sibilant or sonorous rhonchus. With the advance, however, of the malady, secretion takes place from the affected tubes, and cough, with more or less abundant expectoration, is added to other phenomena.

Small malignant growths within the lungs, even if numerous, yield no distinctive physical indications of their presence. They may, however, give rise to congestion, cedema, or inflammation in their vicinity, and may hence become revealed. Larger tumours are often solitary, and limited therefore to one locality; but they may involve the whole of one lobe, or even more, of a lung. These, like smaller growths, are often associated with other local morbid conditions, which increase their apparent bulk and add to or aggravate the patient's symptoms.

When malignant tumours are of sufficient size to be recognisable by physical signs, we find, in many cases, that there is dulness on percussion over the region which they occupy, and that there is also a total absence of healthy respiratory sound, of tubular breathing, of all forms of

rhonchus and crepitation, and of bronchophony, pectoriloquy, and vocal fremitus. The local indications, indeed, are rather those which we are accustomed to regard as characteristic of pleural effusion than those which we usually associate with consolidation. The explanation of this peculiarity lies in the fact that malignant growths usually form solid masses, the bronchial tubes which permeate them being compressed or otherwise obliterated; and that hence they are as distinct acoustically from the lung-tissue as is an accumulation within the pleura, or the heart itself. There are many exceptions, however, to this rule—some due to the presence of surrounding inflammatory changes, some to the continued patency of tubes and to the greater or less abundance of secretion in them, some to the formation of vomicæ. The presence of malignant tumours in the lungs necessarily causes, sooner or later, dyspnoea and cough, with expectoration which varies in character—being sometimes at the beginning mere bronchial mucus, but later on becoming muco-purulent, and at length purulent, hemorrhagic, and fetid. Occasionally the sputa are glairy, and green, yellow, or brown, exactly like the fluid which is perhaps accumulating at the same time in the pleura. The general symptoms of malignant disease of the lungs are, for the most part, those of gradually increasing debility and emaciation often associated with those of hectic fever, the patient at length dying exhausted, and sometimes before death passing into the typhoid state. Death may be due, however, less to the progress of the cancerous growths than to the secondary phenomena, such as pleural effusion and bronchitic obstruction, to which they give rise; and hence it may occur at a comparatively early period of the disease, or, at all events, before the opportunity for accurate diagnosis has presented itself.

It has been assumed, in the foregoing account, that the disease has primarily or mainly implicated the lungs or pleuræ. But when the thoracic affection is secondary to more advanced disease elsewhere, it often fails to reveal itself by symptoms. Indeed, the diagnosis of pulmonary or pleural malignant disease is often a matter of extreme difficulty, and in most cases only to be arrived at by a very careful collation of all the facts of the case, and by close and continuous observation of the patient's progress. The presence of malignant growths elsewhere of course furnishes a most important clue. This clue is not likely to fail in cases in which the pulmonary affection is secondary and comparatively unimportant; but it may be wholly absent where its aid is most needed. Careful examination, however, should be made periodically in such cases, for often in their progress enlargement of glands at the root of the neck, in the axilla or thoracic parietes, or development of growths in connection with the ribs or connective tissue of the thoracic walls becomes manifest, and throws a new and important light upon phenomena which were hitherto obscure.

*Treatment.*—The treatment of malignant disease of the lungs and pleuræ needs no special description. The treatment, already considered, of pleurisy, bronchitis, and pneumonia includes in some measure that of

the several affections which have just been discussed ; with the important reservation that all that can be done for malignant disease is palliative, and that therefore lines of treatment which may be pushed with advantage in the case of the inflammatory affections must be cautiously followed in respect of their malignant counterfeits. The relief of pain and discomfort, and the administration of nourishment, should be our chief aims.

## X. PARASITES. HYDATIDS<sup>1</sup>

*Morbid anatomy.*—The only parasitic disease of the lungs which has any practical interest is that due to hydatids. This is of exceedingly rare occurrence in England, but is common in Australia. There is usually only one tumour present, and this is said to be generally situated in the lower part of the right lung. The hydatid tumour may attain the size of a large cocoa-nut or exceed it ; may be situated (as it usually is) wholly within the substance of the lung ; or, originating beneath the visceral pleura, may form, as it were, an outgrowth from the lung into the pleural cavity. The walls of the cyst which contains the parasite vary in thickness and density. This is usually solitary. Hydatids of the lungs, like hydatids elsewhere, are liable to cause serious consequences, either by the pressure they exert, or by undergoing suppuration, or by discharging their contents into the pleural cavity or bronchial tubes ; they are also liable to undergo degenerative changes, with gradual contraction and calcification.

*Symptoms and progress.*—Hydatid tumours of the lungs, when small, occasion little or no uneasiness, and necessarily therefore fail to be discovered. But as they enlarge they are after a while apt indirectly to cause bronchitic symptoms and occasional attacks of hæmoptysis, and thus a series of symptoms which are exceedingly liable to be mistaken for those of phthisis. Their recognition may be rendered possible either by the special features of the tumours to which they give rise, or by the sudden expectoration of their contents. An hydatid cyst is always tense and of a globular or ovoid form, and, hence, when it attains any considerable size, tends, on the one hand, to cause circumscribed bulging of the thoracic parietes with widening and protrusion of the corresponding intercostal spaces, and, on the other hand, to displace the mediastinum and diaphragm. The localised bulging of the chest-wall, with the possible detection of fluctuation and hydatid thrill, and the circumscribed dulness on percussion which probably transgresses the median line of the thorax, without extending at the same time to its summit, are strongly indicative of the presence of a pulmonary hydatid ; especially if these conditions have come on without febrile or acute symptoms, and the general health

<sup>1</sup> For fuller details in reference to the pathology, diagnosis, and treatment of hydatids, we must refer the reader to the account of these parasites given farther on amongst the diseases of the liver.

of the patient has been and remains good. There is also over the area of dullness total absence of respiratory sound and vocal fremitus. It is stated that the voice sometimes presents at the margins of the tumour an ægophonic character. The signs above enumerated are not absolutely pathognomonic of hydatids; for they may be equally present (occasionally at least) in cases of circumscribed empyema or solid tumours. The rupture of an hydatid cyst and the escape of its contents into the bronchial tubes is attended with sudden suffocative cough and profuse expectoration, which may, according to circumstances, be limpid and watery, or purulent, and may contain echinococci, hydatids, or fragments of hydatid membrane. The detection of the parasites, by the naked eye or microscope, necessarily removes all doubt as to the nature of the case.

Hydatid tumours not unfrequently undergo cure—sometimes by spontaneous retrogression, sometimes after the discharge of their contents by the bronchial tubes or some other route. On the other hand, the patient may die, suffocated by the sudden irruption into the air-passages, or exhausted by long-continued suppuration, or from empyema due to the rupture of the cyst into the cavity of the pleura.

It is in many cases impossible to distinguish accurately between hydatid tumours of the base of the right lung and those developed in the upper part of the right lobe of the liver. For the latter often protrude far into the chest, displacing the diaphragm and base of the lung upwards; and cause marked bulging and dullness of the corresponding region of the thorax. Moreover, they are apt to perforate the diaphragm and to open either into the pleural cavity or into the lung itself, and in the latter case to discharge their contents by expectoration. When, however, hepatic hydatids are expectorated, biliary colouring matter is usually sooner or later mingled with them. On the other hand, hydatid abscesses of the base of the lung may perforate the diaphragm and so lead to the formation of abdominal abscesses.

*Treatment.*—There is little room for special treatment in the case of pulmonary hydatids. When, however, they are recognised as obvious tumours, they may be treated on the same principles as hydatids of the liver—a subject fully considered farther on.

---

## XI. BRONCHIECTASIS. (*Dilatation of Bronchial Tubes*)

*Causation and morbid anatomy.*—It is theoretically an easy matter, but practically very difficult, to draw the line between simple dilatation of bronchial tubes and vomicæ which have become lined with a smooth membrane, and are in direct continuity with tubes. We make this distinction incidentally only, for our description of dilated tubes will embrace without distinction the several morbid conditions which are commonly confounded under the term.

Dilated tubes, then (using the term in its widest sense), may be

arranged in three categories: namely, 1st, that in which the dilatation involves the tubes in their whole length, and is consequently cylindrical or moniliform; 2nd, that in which it affects only the terminal portions of the tubes, and assumes a globular form; and 3rd, that in which the expansions are large, irregular in shape, and communicate with one or more bronchia.

1. In the first of these varieties, the dilatation, which usually commences in tubes of the first or second order, is continued thence, with little or no interruption, through the succeeding tubes almost to their terminations in the air-cells. It is generally relatively greater in the smaller than in the larger tubes; the larger tubes indeed often being scarcely implicated, while the smaller measure from  $\frac{1}{4}$  to  $\frac{1}{2}$  inch or more in diameter. Hence the affected canals form, in some cases, a series of hollow cylinders of nearly uniform calibre; in other cases a series of channels which actually increase in diameter towards their distal extremities, where probably they undergo in addition sudden and considerable enlargement. The dilatations are rarely, however, entirely uniform, but generally present a somewhat irregular or moniliform condition. The parietes of the dilated tubes vary in character; sometimes they are generally thickened, sometimes exceedingly thin and delicate, sometimes the mucous membrane is fairly normal, sometimes thick, congested, and pulpy. In the larger tubes the fibrous and muscular bands often stand out in strong relief, the interstices being correspondingly deep, and occasionally forming distinct pouches. This form of dilatation seldom involves both lungs at the same time, and still more seldom the whole of one lung. It is most frequently met with in the lower and middle lobes, and even then is usually restricted to certain of their tubes only. The dilated canals are in some cases surrounded by fairly healthy, in some by emphysematous, in some by collapsed, lung-tissue. Cylindrical dilatation of the bronchial tubes is probably always secondary to chronic bronchitis, and more especially to capillary bronchitis with abundant accumulation of fluid; and is due primarily to the concurrence of inflammatory enfeeblement of the bronchial walls, and their distension by accumulated fluid contents.

2. In the second variety, the expansion is limited almost exclusively to the terminal portions of the smallest bronchial tubes and bronchial passages. The dilatations are globular or nearly so in form, and vary perhaps from the size of a small pea up to that of a filbert; they present a smooth internal surface; their parietes are comparatively thick, dense, and opaque; and for the most part they communicate severally with a single bronchial tube, the orifice of communication with which is sometimes small and difficult to find. In some cases such dilatations are scattered irregularly throughout emphysematous or otherwise diseased lung-tissue; in some they are grouped in some corner of a lung, or they involve the whole of a lobe, or even of a lung. The lower lobe is most frequently affected. In the best marked cases the affected organ is diminished in size, and riddled with globular cavities which are separated from one another by airless, collapsed, indurated lung-tissue. The history

of these cases is usually very obscure ; but there is good reason to believe that they originate, not in ordinary chronic bronchitis, but in either atelectasis, collapse, lobular pneumonia, or some other such condition. And it is probable that, in the first instance, the accumulation of muco-purulent fluid or of pus within the terminal bronchial tubes leads to the destructive ulceration of their walls and of the tissues which surround them ; that thus small cavities or vomicæ, communicating with tubes, are formed within the solidified tracts of lung-substance ; and that finally each cavity attains a certain size, assumes a definite form, and becomes lined with a membrane continuous with that of the bronchial tubes.

3. The third variety comprises those cases in which the lung contains one or more cavities, irregular in shape, and various but often considerable in size, each of which opens freely into one or two bronchial tubes. In some instances these cavities are solitary, situated in the apex, base, or elsewhere in the substance of the lung, and surrounded by or imbedded in dense fibrous or cicatricial tissue. In other instances the whole of one lobe, or the whole of a lung, contracted and cirrlosed, is studded with them. They are often lined with a perfectly smooth, polished membrane, continuous with that of the communicating bronchial tubes, but sometimes exhibit an eroded or flocculent surface. In some cases they and the bronchial tubes connected with them present a thick, pulpy, deeply-congested lining, which may perhaps be undergoing excoriation. These cavities are not of course, strictly speaking, simple dilatation of tubes ; but obviously originate in vomicæ—tubercular, pneumonic, gangrenous, or other. They are always surrounded with indurated tissue, and in a considerable number of cases are associated with obvious or advanced cirrhosis.

The determining cause of the several forms of bronchiectasis which have been considered is no doubt disease involving the bronchial tubes themselves—disease attended with softening or destruction of their walls, and distension of their channels from undue accumulation of fluid within them. Yet it cannot be denied that other influences co-operate in some degree with these, the most efficacious of them being the constant tendency of a retracted side to recover its form, partly by its inherent elasticity, partly under the influence of the inspiratory efforts. It must be remarked, however, that this latter influence can scarcely be operative unless the lung-tissue generally be indurated and reduced in bulk, and that in spite of it many vomicæ contract, and some possibly cicatrize.

*Symptoms and progress.*—It will probably be gathered from the foregoing account of the morbid anatomy and causation of bronchiectasis that its special symptoms are in almost all cases necessarily mixed up with those of the maladies out of which it arises and with which it is associated. Moreover, its own symptoms are not very characteristic. Those which may especially be looked for are shortness of breath, cough, and abundant muco-purulent expectoration, not unfrequently mingled with blood, and occasionally fetid with a fœtor which is scarcely, if at all, distinguishable from that of gangrene. This is believed to be due to

decomposition of the retained sputa. The physical signs which may present themselves are retraction and immobility of one side or of a portion of one side of the chest, dullness on percussion, with large crepitation or gurgling, and other indications of the presence of vomicæ. It must not be forgotten, however, that difficulty of breathing may be scarcely noticeable if one lung continue perfectly healthy, and that distinct indications of the presence of cavities are not likely to be observed if the cavities be small or deeply-seated and surrounded with comparatively healthy tissue. Profuse and repeated attacks of hæmoptysis, due to intense inflammation and congestion of the lining membrane, or to its erosion, are not uncommon in the last of the three varieties of bronchiectasis, and occasionally cause death. The diagnosis of dilated tubes rests on a careful consideration of the history of the case, on the slow progress of the pulmonary lesion, or its limitation to one lung, often to its lower half, and on the profuseness, long continuance, and often fetor of the expectoration.

*Treatment.*—No special treatment is required in bronchiectasis. For the most part the rules which have been laid down for the treatment of chronic bronchitis are applicable here.

---

## XII. EMPHYSEMA

*Causation and morbid anatomy.*—Emphysema is due to the dilatation and rupture of the air-cells of the lungs. Two forms of it have been described, namely, the *interlobular* and the *vesicular*: in the former of which air is extravasated into the interlobular spaces, whilst in the latter the dilated and ruptured vesicles communicate simply with one another.

1. *Interlobular emphysema* takes place only in those cases in which the pulmonary lobules are separated from one another by distinct intervals occupied by connective tissue. This anatomical peculiarity exists in the lungs of young children and of some of the lower animals, but is absent from the lungs of human adults. Interlobular emphysema is, therefore, a phenomenon of childhood only, and is occasionally observed, post mortem, in cases of whooping-cough, lobular pneumonia, and capillary bronchitis, especially where there have been repeated violent paroxysmal attacks of coughing. The escape of air into the interlobular spaces is indicated anatomically by their marked dilatation and their occupation by what looks like strings of air-bubbles. The amount of emphysema present varies greatly. In some cases, on section of the lung, merely a line or two of emphysematous tissue is observed. In other cases the lobules are extensively isolated from one another by a network of such tissue, and a similar mapping-out of them may be recognised on the surface of the lung. Occasionally the emphysematous condition extends along the connective tissue which surrounds the bronchial tubes to the root of the lung, and thence diffuses itself into the mediastina, neck, face, trunk, and

elsewhere. The latter phenomenon is more frequently the result of gross mechanical injury than of infantile pulmonary disorders; and under such circumstances is observed in adults as well as in young children.

2. *Vesicular emphysema* is a much more common, and, on the whole, a much more serious affection than the last. It occurs, with certain differences of character, under a variety of conditions. Thus, it is not unfrequently met with in the lungs of persons dead of acute bronchitis; it is an all but universal attendant on the chronic form of that disease; it is one of the lesions which often accompany old age; it is a frequent associated phenomenon of the degeneration of tubercular masses, or of the contraction, from whatever cause, of circumscribed bits of lung; and it is also, as we believe, an occasional sequela of the obsolescence of scattered miliary tubercles. Under most of these conditions there has been persistent cough; under several of them, enfeeblement of the walls of the air-vesicles or their involvement in destructive processes.

a. The lungs of persons dead of acute bronchitis are often found much distended with air. They completely fill the portions of the thoracic cavity allotted to them, and do not collapse even after they are removed from the body. The air-vesicles are generally distended to the full, and the lung-tissue consequently is light, pale, and unusually spongy. This condition is always associated with obstruction of the bronchial tubes by secretion, and is primarily due to the comparative facility with which air is then drawn into the ultimate tissue of the lungs during inspiration, and the comparative difficulty with which it is then discharged during expiration. The appearance here referred to is very commonly regarded as an indication of emphysema. It is obvious, however, that there can be no disease of the air-cells, no vesicular emphysema, so long as the air-cells are simply distended and their walls remain sound. But when, as often happens at length, textural changes are superadded, when the walls of the air-cells become attenuated, bulging, perforated, and intercommunications between neighbouring cells established, emphysema is really present. Nevertheless, it is not always easy, either with the naked eye or with the microscope, to distinguish between mere over-distension of the air-cells and the beginnings of actual emphysema.

b. The lungs of patients who have long suffered from chronic bronchitis are almost always emphysematous. When the emphysema is advanced and well-developed, the lung is usually of large size and exceedingly irregular in form—the increase of size and the irregularity being both due to the formation of clusters of emphysematous vesicles, which cause lobular, and in some cases pedunculated, protrusions from various parts of its surface. These are usually most abundant upon the anterior and outer surfaces of the lung, and especially upon its diaphragmatic aspect. If the lung be full of air, the prominence of these clusters is unmistakable, and the relatively enormous size of their vesicles obvious on even casual inspection. On section, the emphysematous tissue collapses much more readily than the healthier tissue around. If the distended lung be dried, before section, the distribution of the emphysema,

not only at the surface but in the interior of the lung, may be easily recognised. The emphysema of chronic bronchitis has its origin, no doubt, in the emphysema of the acute disease, and comparatively slowly attains extreme development; and, like the last, it consists essentially in the attenuation and perforation of the walls of the air-cells, the distension of the multilocular cavities thus produced, and the atrophy and disappearance, to a large extent, of the capillary networks of the affected regions. The emphysematous blebs may, roughly speaking, vary in size from that of a tare or pea up to that of a filbert or walnut.

c. It is not uncommon to find a certain amount of emphysema in the lungs of old people who have never suffered materially from bronchitic symptoms. The emphysema here, however, is rarely extensive, and is often limited to the formation of fringes of emphysematous vesicles along the anterior and other sharp edges of the several lobes, and to the appearance of solitary vesicles scattered thinly over the general surface in connection with black pigmentary patches. When tubercular and other indurations and contractions take place in relation with any part of the pulmonary surface, so as to cause irregularity, puckering, and fissuring, well-marked emphysema (differing in no respect, except distribution, from that of chronic bronchitis) almost invariably manifests itself in the immediate vicinity. This variety of emphysema is most common at the apex. Again, emphysema arises in general but comparatively slight chronic disorganisation of the lung-tissue, general slight cirrhosis, or the obsolescence of widely distributed miliary tubercles. In these cases, as has been previously pointed out, the lung-texture is coarse, permeated by a fine network of what looks like cicatricial tissue, in the meshes of which the dilated and ruptured air-cells are contained.

The ætiology of emphysema is a subject of much interest, and has largely occupied the attention of medical men. The theories which have been proposed in reference to it may be divided into three groups: the first of which attributes it to the dilating force exercised during the act of inspiration, the second to the pressure exerted during the act of expiration, the third to nutritive impairment of the walls of the air-vesicles.

1. When we consider that the healthy lung is accurately adapted to the cavity which contains it, and that no enlargement of the chest voluntarily effected can possibly dilate injuriously the healthy lung within it, it is impossible to conceive that the emphysema of at least uncomplicated bronchitis can be referred to the force with which the lungs are inflated. Matters are, however, somewhat different when a lung, reduced in bulk by pleuritic adhesions or textural changes, is subjected to the rhythmical efforts of the corresponding thoracic wall to expand. It is conceivable then that while those parts of the lung which are most firmly compressed or most dense from consolidation would undergo little or no consequent change, those which are comparatively little compressed, or which are still fairly crepitant, might undergo disproportionate expansion, their air-cells might dilate, and their parietes become attenuated and finally ruptured. This, indeed, is the explanation commonly assigned

to that form of emphysema which is developed in the vicinity of obsolescent tubercular masses and other patches of contracted indurated lung-tissue. It may be observed, however, on the other hand, that when, in lungs bound down and compressed by dense adhesions, portions of lung where the adhesions are thinnest expand and protrude beyond the general level, emphysema is certainly not commonly observed.

2. During ordinary expiration, when the lung-tissue retains its normal elasticity, and the bronchial and other passages are freely permeable, the air-cells are subjected to very little pressure. In all those acts, however, in which with closed glottis the expiratory muscles are called into vigorous action, the pressure on the surface of the air-cells and air-passages becomes augmented, and in some cases very greatly augmented. The acts to which we here refer are, in ascending order, speaking and shouting, the blowing of wind instruments, the expiratory shocks of coughing, and the straining efforts which attend defæcation, parturition, and other forms of violent muscular exertion. But in these cases, again, if the passages are permeable the pressure is uniformly distributed, and injury to air-cells is little likely to result unless some of them have been previously impaired as to their power of resistance by morbid changes. The conditions, however, are altogether different when violent expiratory efforts are made, and made habitually, in the presence of obstructive disease of the bronchial tubes, whether the obstruction be due to accumulation of mucus or other matters within them, to thickening of their lining membrane, or to their compression by morbid growths external to them. For it is easy to see that then while, during violent expiratory efforts, large portions of the lung whose tubes are little obstructed become comparatively empty, other portions (scattered probably among them) whose tubes are more completely obstructed remain distended, and become in consequence unduly exposed to the compressing force exerted by the thoracic parietes. For equal extents of surface a globe holds more than any other solid figure; it is obvious, therefore, that if a full globe be compressed it must either yield or burst. The same remark applies to a distended air-cell or a group of distended air-cells; and hence it is obvious that the effect of the expiratory compression of groups of full air-cells in connection with obstructed tubes must necessarily result in the expansion and attenuation of their walls, and sooner or later probably in their rupture. It is doubtless to this cause in large measure that the emphysema of bronchitis and the interlobular emphysema of childhood are due.

3. Many years ago Mr. Rainey demonstrated the occurrence of fatty degeneration in the walls of the dilated air-cells in some cases of emphysema. We have already alluded to the occurrence of emphysema in connection with cirrhosis and obsolescent miliary tubercles. But indeed it will be admitted without further formal proof that the walls of air-cells are liable to get weakened, and to lose their ready distensibility, under these and many other conditions, such as old age, and various forms of inflammatory and other processes. It is too obvious to need argument

that enfeeblement of the walls of the air-cells must co-operate powerfully with the mechanical causes already discussed in the production of emphysema, and must, especially when of partial distribution, render even normal violence of expiration a source of danger.

In concluding this brief discussion of the causes of emphysema it must be added that, although we have considered them separately, they probably always act in concert. Thus, before the expiratory acts can cause compression and rupture of groups of air-cells, these must have been distended with air by more or less powerful efforts of inspiration; and even if the air-cells were previously healthy, their mechanical distension, attenuation, and laceration must result in impairment of their powers of resistance for the future.

*Symptoms and progress.*—Emphysema in its slighter degrees is often present without causing distinct symptoms. Thus, in the limited emphysema which attends the obsolescence of tubercle, and in that which comes on in old age, there is often absolutely no sign to indicate its presence; and, even in the emphysema of bronchitis, there are often at first, and even for a considerable time, no phenomena apart from those of persistent bronchitis to justify its diagnosis. When, however, emphysema becomes considerable either in degree or in extent it can scarcely escape recognition, notwithstanding the fact that even then its symptoms are mainly those of bronchitis.

The physical signs of advanced emphysema comprise alterations in the form and movements of the chest, together with percussive and auscultatory peculiarities. The chest tends to get dilated in all its dimensions, rounded from above downwards as well as horizontally, the ribs at the same time acquiring a less oblique direction than in health; the form which it assumes is that to which the term 'barrel-shaped' has been applied. The shoulders become elevated, and the muscles of expiration (more particularly those of the neck and shoulders) unduly prominent. At the same time the limits of the respiratory movements become narrowed, the chest during expiration retaining still the distended or barrel-like condition, and during inspiration undergoing little enlargement. On percussion, there is usually increase of resonance over the chest, and more especially over those portions of it which correspond to emphysematous areas; and the precordial dulness is diminished in extent, or even abolished. The respiratory sounds are enfeebled.

The symptoms referrible to this lesion are shortness of breath, increased by exertion, and culminating at times in asthma-like attacks; duskiness and pallor of skin; and disposition on the slightest exposure to suffer from bronchitic attacks. Further, there is usually feebleness of pulse, and tendency to emaciation. The presence of any considerable amount of emphysema interferes seriously with the readiness of transmission of the blood through the lungs, and hence gradually the right side of the heart becomes hypertrophied and dilated, the cervical and other systemic veins get distended with blood, the circulation is impeded in the capillary vessels of the extremities and internal organs, and general

anasarca, congestion of liver with jaundice, and congestion of kidneys with albuminuria, supervene. Indeed, the consequences of emphysema are almost identical (excluding congestion of the lungs) with those of mitral valve disease.

*Treatment.*—The treatment of emphysema must necessarily be indirect. We cannot, either by drugs or otherwise, restore the affected air-cells to their former condition. But what we can do, in many cases, is by suitable medicinal and hygienic treatment to cure or relieve the bronchitis which is so often associated with it, to prevent the recurrence of such attacks for the future, to relieve cough and dyspnœa, and to promote the general health. In addition, we may forbid all violent exercise and over-exertion. Easy circumstances, early hours, wholesome but not excessive diet, gentle exercise, warm clothing, a genial climate, together with the careful avoidance of everything calculated to give cold, constitute the main elements in the successful management of those who suffer from emphysema. For the treatment of its complications we must refer to what is said under their respective heads; and especially we must refer to the articles on bronchitis and asthma.

---

### XIII. CONGESTION

*Causation and morbid anatomy.*—Congestion always co-exists with inflammation. It frequently occurs, however, under other circumstances; and it is this variety that we propose now to consider.

1. *Congestion of the larynx, trachea, and bronchial tubes.*—Simple hyperæmia of these organs may result from obstructive disease of the right side of the heart or any other condition which causes accumulation of blood in the veins leading from these parts, or it may be a sequela of repeated attacks of inflammation.

2. *Congestion of the lungs* is an expression in constant use, but is probably generally applied to cases of bronchial or pulmonary inflammation. Simple congestion, however, is of frequent occurrence, and is often a serious complication of other morbid conditions. It is an early and grave consequence of mitral valve disease, and other affections of the left side of the heart. It is a frequent complication of typhus and other infectious fevers, and even of the typhoid state. It doubtless also persists in some cases for a longer or shorter period as a sequela of inflammation.

Congestion secondary to heart-disease is for the most part general, and is often followed by rupture of the small vessels of the lungs and extravasation of blood. It leads consequently to the condition known as pulmonary apoplexy and to hæmoptysis. Further, it predisposes to pneumonia. The congestion which takes place in fevers is commonly termed 'hypostatic,' from the fact that it particularly affects the dependent, and generally, therefore, the posterior and lower parts of the lungs. It is due, like the congestion which in the same affections occurs in other

depending parts of the body, to feebleness of circulation and the disposition which the blood then has to yield to the influence of gravity. The affected portions of the lungs become dark, almost black with congestion, cedematous, more or less devoid of air, heavy and lacerable; but they maintain their bulk, and generally crepitate in some degree. Not unfrequently this condition passes into pneumonia, and even gangrene. Congestion of the lungs, whether in connection with heart-disease or febrile states, is always a matter of serious importance, partly because it indicates that there is something in the stage or nature of the malady which threatens danger, partly because it gives rise itself to serious symptoms, partly because it is apt to end, as the case may be, in pulmonary apoplexy, gangrene, or inflammatory consolidation.

*Symptoms.*—Of itself congestion of the air-passages is probably unimportant, leading at most to increased secretion from the mucous surface and its glandular follicles, and to habitual tendency to cough and hawk, especially on rising in the morning. It is chiefly serious because its presence greatly increases the liability to inflammation. The evidences of congestion of the lungs are mainly difficulty of breathing, with lividity and other asphyxial phenomena, cough with watery expectoration, and the presence of crepitating râles, either generally distributed, or limited to or more pronounced in the lower and back parts of the lungs. The supervention of apoplexy, pneumonia, or gangrene will be recognised by its special indications.

*Treatment.*—Little can be done directly to relieve these mechanical congestions. In cardiac cases, it is sometimes useful to remove blood by leeching, cupping, or venesection, or to act on the bowels or other emunctories. But, for the most part, all we can do is to treat the heart-affection on the principles elsewhere laid down, and the febrile disorder according to its general indications.

---

#### XIV. DROPSY. HYDROTHORAX

*Causation and morbid anatomy.*—Œdema of the respiratory organs constantly occurs as an incident of the inflammatory process, of tuberculosis, and of the growth of malignant tumours. Œdema of the larynx, which is so often a cause of death, is almost without exception the result of inflammation either of the larynx itself, or of parts in its immediate neighbourhood; pneumonic consolidation of the lung is usually attended with œdema of the lung-tissue surrounding the consolidated district; and pleurisy is rarely, if ever, unaccompanied by serous effusion into the pleural cavity.

Independently of inflammatory dropsy, however, which does not now concern us, there are other forms of dropsy, for the most part of mechanical origin, which are sufficiently important in their effects to call for a few remarks. Dropsy of the respiratory organs, like dropsy of other parts, may be due, equally with congestion, to certain forms of

cardiac disease and other affections involving obstruction of veins; it may arise, also, in the course of renal disease; and occasionally originates in mere anæmia.

1. *Œdema of the larynx* may occur in the course of renal and heart diseases, and in those cases in which, from the presence of mediastinal tumours, the vena cava descendens or the innominate veins are obstructed; and possibly may, even in its uncomplicated state, cause dangerous symptoms and death. Generally, however, when serious symptoms arise, inflammation has become superadded to the dropsy; and, indeed, the supervention of inflammation doubtless constitutes the chief danger of this limited dropsy.

2. *Œdema of the lungs* is a frequent accompaniment of general anasarca, from whatever cause; but is especially common in scarlatinal affection of the kidneys and other forms of Bright's disease; and may occur in a high degree, even when there is little or no dropsy observable in other parts of the body. An œdematous lung is usually voluminous, heavy, and pale, and, on section, large quantities of serous fluid mingled with air-bubbles drain away or may be squeezed out. It contains much less air proportionately to its bulk than natural, but is rarely quite devoid of air in any part. If the lung be at the same time congested, it combines the characters of congestion and œdema. In hypostatic congestion, which has already been described, there is usually such a combination. Œdema, like congestion, sometimes results in a form of pneumonic consolidation, and not unfrequently in a condition of carnification or collapse.

*Pleural dropsy, or hydrothorax*, occurs under the same circumstances as œdema of the lungs, and is often associated with it in the sense of being complementary to it. That is to say, hydrothorax, which is a serious and frequent item of general dropsy (whether cardiac, renal, or pulmonary), and tends for the most part to arise whenever œdema of the lungs tends to arise, serves nevertheless mechanically to exclude the latter condition, and conversely. Thus if there be much pulmonary œdema there is probably little pleural effusion; if much pleural effusion, little pulmonary œdema; and if there be coincidence of pleural and pulmonary dropsy on the same side, the latter is limited to that portion of lung which lies above the level of the pleural exudation, the rest of the lung probably being compressed, and void both of air and of excess of fluid. And further it often happens that, if one lung be bound down by adhesions, the other being free, there is pleural dropsy exclusively upon the one side, pulmonary œdema exclusively upon the other. Occasionally hydrothorax is so considerable that it distends the pleural cavity and causes total collapse of the lung.

*Symptoms.*—The symptoms of œdema of the larynx, so far as they are important, have already been fully considered. Those of œdema of the lungs are nearly identical with those of congestion of the same organs. There is gradually increasing difficulty of breathing, with lividity of surface and other symptoms of defective aëration of the blood—symptoms

which need not be re-discussed, but which, if not relieved, increase in severity until death takes place. There is usually also, sooner or later, more or less cough, with expectoration of thin serous fluid. The presence of œdema does not necessarily entail local indications; the chest may be perfectly resonant, the breath-sounds as nearly as possible healthy. Still crepitation may generally be recognised, sometimes 'pneumonic' crepitation, especially behind and below; and with the occurrence of consolidation the indications of that condition are necessarily developed.

The general symptoms to which pleural dropsy gives rise are in the main those of pulmonary œdema. The local signs are those which have already been described as indicative of the presence of fluid in the pleural cavity (page 395). It may be observed that whenever difficulty of breathing and other signs of slowly developing asphyxia arise, in the course of renal or cardiac disease, or of suspected general tuberculosis, or malignant growths, it is important to examine the thorax carefully in reference to the probability of pleural dropsy being present. And further, in relation to this point, it is worth while to remark that there is often much more fluid in a pleural cavity than might be suspected from casual examination. For, in determining its presence and amount, the patient is usually made to sit up in bed and bend his trunk forwards—a position which necessarily throws the fluid forwards and reduces the height of the level of dulness behind in relation to the landmarks which usually guide us.

*Treatment.*—The treatment of dropsy of the larynx, lungs, and pleuræ, resolves itself into that of the diseases which give rise to it. We must refer, therefore, to observations made elsewhere upon the treatment of inflammations and tumours of these organs, and upon that of heart-disease, bronchitis, and albuminuria. When, however, even in advanced heart or kidney disease, or other affections, the patient with dropsical accumulation within the pleura is suffering much from dyspnœa, great, even though temporary, relief may often be given by the performance of paracentesis. The removal of only a few ounces of fluid by the aspirator may be sufficient for the purpose.

---

## XV. PULMONARY COLLAPSE. ATELECTASIS

*Causation and morbid anatomy.*—Under a considerable variety of circumstances, portions of the lungs become void of air and shrink, assuming an appearance to which the term *carnification* has been commonly applied.

1. The simplest form of this condition is observed in a lung or part of a lung compressed by accumulation of fluid within the pleura. It is much reduced in bulk, wrinkled and livid on the surface, uniformly smooth, dark, and flesh-like on section (the bronchial tubes and larger vessels being compressed equally with the vesicular texture), tough but flabby in consistence, heavier than water, and capable of being reinflated through the bronchial tubes which lead to it.

2. A second form is that which is frequently observed in the lungs of patients dead of bronchitis, fevers, or other affections in which, from debility or blocking up of some of the smaller bronchial tubes, respiration has been incompletely performed. Here the collapse does not, as a rule, involve any considerable continuous tract, but affects scattered groups of lobules which are usually most abundant and largest in the lower portions of the lungs. In such cases the lungs present considerable irregularity of surface: depressed livid-looking polygonal patches alternating with elevated tracts of comparatively pale and crepitant tissue. On section, the depressed areas are found to correspond to dark-coloured, airless, smooth, tough, carnified patches, which extend to various depths into the substance of the lung. In many cases a few such patches of collapse only are visible; in others the collective bulk of collapsed lung-tissue is very considerable.

Frequently, no doubt, the condition of the affected bits of lung here referred to is identical with that of lungs compressed by pleural effusion; and in nearly all cases inflation may be readily performed. It must not be forgotten, however, that such collapse often takes place in lungs which are already congested or œdematous, when of course the shrinking is less pronounced, and the tissue is more juicy and lacerable than in simple collapse. Nor must it be forgotten that when the collapse is a complication of bronchitis, there is a tendency for it to pass into, or to be associated with, lobular pneumonia; and that then patches of apparently pure collapse are often associated with patches of distinct lobular pneumonia and others presenting gradations between these extremes. The main physical distinctions between lung-tissue consolidated from collapse and pneumonic lung are: the shrunken condition, the smooth, homogeneous, shiny, reddish-black sectional surface, and toughness of the former, the expanded, granular, lacerable and, for the most part, pale reddish or greyish marbled aspect of the latter.

The explanation of the production of the form of collapse now under consideration is not far to seek. Dr. Gairdner's theory is simple, and has found general acceptance. According to it, the smaller tubes get more or less completely filled with mucus, which acts in each case as a valvular plug, preventing the passage of air beyond it during inspiration by becoming then more tightly wedged in the narrowing tube, but allowing the escape of air from the implicated air-cells during expiration by being then driven into the wider portion of the tube above. It is not quite clear, however, that mucus is generally capable of performing this two-fold action; nor is it essential that it should so act in order that collapse shall be produced. The simple but complete and prolonged obstruction of a small tube is amply sufficient to cause collapse of the portion of lung to which it leads—the obstruction preventing both ingress and egress of atmospheric air, and the tissues beyond gradually absorbing that which is imprisoned within them.

3. A third form of what may also be conveniently termed collapse is known by the name of *atelectasis*. This is really the persistence of the

fœtal state of the lung, in which the condition of things is little, if at all, distinguishable from what obtains in simple collapse.

*Symptoms and progress.*—In discussing the morbid anatomy and symptoms of collapse, it is so usual to confound it with lobular pneumonia (with which it is frequently associated), that the result is less an account of collapse than of inflammation. Collapse is, for the most part, a mere consequence of other lesions, and gives rise to but few distinctive symptoms. Nevertheless, there are some cases in which, doubtless, its occurrence aggravates the patient's symptoms and diminishes the chances of his recovery. This is more especially the case in bronchial affections, hooping cough, measles, and the like, occurring in young children. For in them, owing to the yieldingness of the thoracic walls, perfect inflation of the lungs under difficulties is often impossible, the flexible framework of the chest failing to respond to the efforts of the inspiratory muscles. The symptoms to which extensive collapse may be expected to give rise are in the main those which attend congestion and œdema, namely, gradually increasing dyspnœa, with the other consequences of defective aëration of the blood. We have already, in discussing the subject of bronchiectasis, adverted to the fact that collapsed lung-tissue, whether the collapse be of the nature of atelectasis, or due to pressure, or bronchial affection, may remain permanently solid; and pointed out that there is good reason to believe that it is in such conditions that bronchiectasis with globular dilatations not unfrequently takes its origin. Extensive collapse of lung-tissue is necessarily associated with depression and comparative immobility of the thoracic parietes in relation with the affected tracts; and hence in young children there not unfrequently results permanent impairment of the form of the chest, the lower half usually becoming contracted in the horizontal plane, while the upper remains normally, or even becomes abnormally, expanded.

*Treatment.*—Pulmonary collapse, apart from the bronchial and other affections which attend it, and the permanent consequences which it sometimes entails, scarcely calls for special treatment.

---

## XVI. HEMORRHAGE. PULMONARY APOPLEXY. HÆMOPTYSIS

*Causation and morbid anatomy.*—Hemorrhage from the respiratory organs may be of two kinds:—first, that in which the blood is yielded by some part of the air-passages or cavities in direct continuity with them; and, second, that in which it takes place primarily into the substance of the lungs.

1. The former is due to congestion, inflammation, ulceration, or injury; and may occur in the course of simple or ulcerative inflammation of the larynx, trachea, or bronchial tubes; or attend syphilitic, carcinomatous, or tubercular affections of the same parts; or take place during the

process of detachment of the membranes of diphtheria or plastic bronchitis, of the discharge of hydatids or of the opening of abscesses. It may be due also to the rupture of an aneurysm into the trachea, bronchial tubes, or pulmonary vesicles. In these cases the hemorrhage takes place, either from numbers of minute vessels, or from one vessel of comparatively large size which has undergone ulceration or rupture.

If the blood thus effused be small in quantity, it is usually mingled with the sputa in the form of spots or streaks. If it be more abundant, it becomes more generally diffused throughout their mass. When profuse it not unfrequently accumulates in the cavities or tubes which yield it, or finds its way by the effects of gravity or inspiration into healthy tubes, and even into those of both lungs. Under the latter circumstances it is apt to coagulate and form solid casts of the channels in which it lies. It is said that blood yielded by the bronchial or other passages may be sucked into air-cells, and thus cause pulmonary apoplexy. This we are not disposed to admit.

2. The second variety of hemorrhage takes place into the intervalveolar texture of the lungs and air-cells; and the extravasated blood tends partly to be expectorated, partly to accumulate in the tissues, producing the condition termed *pulmonary apoplexy*. This form of hemorrhage attends pneumonia, but it is rarely excessive in that disease, or productive of apoplexy. Pulmonary apoplexy is much more common in lobular pneumonia and pyæmia. Its most frequent cause, however, is heart-disease, attended with impediment to the passage of blood through the left cavities, or with extreme feebleness of circulation. Further, pulmonary apoplexy not unfrequently complicates Bright's disease in its advanced stages, embolism of the pulmonary artery, and those cases in which, from debility or other causes, there is a disposition to the formation of coagula in the vessels generally.

Pulmonary apoplexy is indicated post mortem by the presence of patches of lung-tissue of various sizes, from that of a pulmonary lobule up to that of a hen's egg, or larger, which are for the most part distinctly limited by the margins of the outermost of the affected lobules, are distended like pneumonic tissue, are of a dark, reddish-black colour like coloured clots unexposed to the atmosphere, contain little or no air, yield a small quantity of sanious perhaps frothy serum on pressure, and are heavy, and more or less brittle or lacerable. The patches display great variety, both in number and in size; and they may occur in any region of either lung, but are more common below than above, and mostly abut on the surface. The presence of pulmonary apoplectic effusions is usually associated with that of moulded adherent clots in the arterial branches leading to them; to the formation of which thrombi, indeed, there is reason to believe that they are often, if not always, due. Apoplectic clots undergo decolorisation, as does blood effused into the subcutaneous tissues; and if small may disappear, leaving behind them some brownish granular pigment only. Sometimes they soften and break down; and generally they induce inflammatory mischief in the lung-tissue around them and the pleural

surface upon which they abut. The surrounding inflammation is sometimes pretty extensive, and the blending of the two morbid conditions may make it difficult or impossible to determine the relation between them, or to define their respective limits.

3. Besides the above varieties of hemorrhage there are others dependent on constitutional disorders which may affect indifferently the parenchyma of the lungs, and the mucous membrane of the air-passages, or are of uncertain origin. Such are the hemorrhages which attend purpura, typhus, small-pox, diphtheria, and similar diseases, that which is said to occur vicariously of menstruation, and that due to diminished atmospheric pressure.

*Symptoms and progress.*—It is not usually a difficult matter to determine whether blood voided by the mouth is derived from the respiratory organs or not. The fact that it is expelled by coughing, and has a florid frothy character; the detection by auscultation of crepitation in one lung, or part of a lung; and (if its source be apoplectic) the recognition of dullness and of the other local indications of pulmonary consolidation, will of course be important aids to diagnosis. Further, careful enquiry into the history of the patient, and examination of his thoracic organs, will, in a large proportion of cases of hæmoptysis, reveal the presence of organic pulmonary, cardiac, or arterial disease. At the same time we must not forget to look to the nose and fauces, in order to be sure that the blood is not yielded by these parts, and especially to determine, so far as may be, the condition of the œsophagus and stomach. Still it is possible to make mistakes in spite of the most anxious care; and it is important, therefore, to bear in mind the following considerations:—first, hemorrhage may take place from the lungs, and yet no other evidence of thoracic disease be present; second, it may, especially if it be from the larger air-passages, be so sudden and profuse that the blood pours from the mouth without any effort at coughing, and even with more or less of the sensation and appearance of sickness; third, although the blood of hæmoptysis is usually described as frothy and scarlet, when it escapes in large quantities its colour may be that of blood in any other form of hemorrhage, and it may be devoid of marked frothiness; and when it has lain in bronchial tubes or cavities, or has been derived from apoplectic effusions, it not unfrequently is dark-coloured or almost black, or of a dull chocolate or coffee-ground hue; fourth, in profuse pulmonary hemorrhage blood may be swallowed in considerable quantity and subsequently vomited or passed by stool; while, on the other hand, in hæmatemesis or epistaxis, blood sometimes finds its way into the air-tubes, and is discharged thence by coughing. When pulmonary hemorrhage is slight, as it generally is in bronchitis, pneumonia, and pulmonary apoplexy, the symptoms to which it gives rise are unimportant; when, however, it is profuse, as it often proves in phthisis or carcinoma, or when an artery or vein is perforated or an aneurysm ruptured, the symptoms and prospects are in the highest degree grave. The patient frequently dies suddenly, either choked by the violent outburst, or rendered syncope from the loss of

blood ; or he sinks at an early period from the effects of repeated hemorrhagic attacks.

*Treatment.*—Many of the varieties of pulmonary hemorrhage do not call for special treatment, and indeed, in the great majority of cases, the hemorrhage must be attacked through the disease to which it is due. This rule applies in great measure even to cardiac and phthisical hæmoptysis. When, however, the discharge is profuse, or threatens to become profuse, or in any way especially dangerous, it calls for prompt treatment. The patient should be kept perfectly still, in the recumbent posture, and every means of quieting the circulation should be adopted ; no exertion, not even that of speaking, should be permitted ; he should be placed in a cool room, and be but little oppressed with bed-clothes ; ice-bags may be applied to his chest ; his food should be unstimulating, and but small in quantity ; he should have cold drinks or ice to suck, and for medicinal remedies such as quiet the circulation or contract the smaller arteries, among which may specially be named lead, gallic acid, digitalis, ergot, and turpentine. Local or general bleeding may, in some cases, be justifiable. The treatment of internal hemorrhage is eminently unsatisfactory.

---

## XVII. PNEUMOTHORAX

*Causation and morbid anatomy.*—The presence of air in the cavity of the pleura is probably always referrible to the existence of some communication between that cavity and the external atmosphere. Thus, it may be due to a wound, such as is made in paracentesis or when the pleura is punctured in the carelessly performed operation of tracheotomy ; or to the opening into the pleura of an abscess already communicating with the exterior, such as one in the parietes of the chest, or an hydatid or other abscess of the liver. Its most frequent causes, however, are the discharge of an empyema through the lungs or thoracic parietes, and the opening of a tubercular or other pulmonary abscess into the pleural cavity. It is said to be caused sometimes by the rupture of emphysematous vesicles, sometimes by the decomposition of fluid or solid matters occupying the pleural cavity.

Pneumothorax, even if it do not commence from empyema, is probably always followed sooner or later by inflammatory effusion into the pleural cavity, and by the formation of pus. If it affect a circumscribed portion only of the pleura there is little or nothing by which it can be distinguished practically or clinically from a pulmonary vomica. The most striking cases are those in which a sudden and free communication takes place between the lung and a pleural cavity which had previously been healthy. The air is admitted into the cavity with each inspiratory act, and, not being again expelled, accumulates at the expense of the lung which undergoes gradual compression, of the mediastinum which becomes displaced to the opposite side, of the diaphragm which is pushed downwards, and of the outer thoracic parietes which become distended and immovable.

The accumulation of air acts, indeed, mechanically in precisely the same way as the accumulation of fluid.

*Symptoms and progress.*—The symptoms which mark the occurrence of pneumothorax are, for the most part, sudden pain or uneasiness in the affected side, but especially the sudden supervention of severe and increasing dyspnœa. They are identical, as nearly as may be, with those of dropsical accumulation, but are much more rapid in their development. When, however, the pneumothorax supervenes on empyema, or occurs within a limited space, no special symptoms may be developed. The physical signs have already been considered. They are mainly, in addition to distension and immobility of the affected side, over-resonance on percussion, absence of respiratory murmur, with cavernous and metallic sounds, and diminution of vocal fremitus. The supervention of empyema, and the accumulation of fluid in the pleural cavity, lead to the production of additional physical phenomena which have already been sufficiently described.

*Treatment.*—The treatment of pneumothorax is in the main that of empyema. When intense dyspnœa comes on rapidly, it may be necessary to remove the accumulated air by paracentesis.

## XVIII. PARALYTIC AFFECTIONS OF THE LARYNX

These affections are very various in their origin. They may be due to mere functional disturbance, as in hysteria and loss of power of phonation from sudden fright or other mental disturbance; to diphtheria; to cerebral disease; to lesions of the pneumogastric trunk, or of the superior or recurrent laryngeal nerves. Further, atrophy of one or more of the laryngeal muscles may take place independently of nervous disorder.

1. *Paralysis of the superior laryngeals.* a. *Bilateral paralysis* is a rare affection, and usually due to hysteria, bulbar paralysis, or diphtheria. The superior laryngeals are the sensory nerves of the larynx, but supply motor branches to the crico-thyroid muscles exclusively, and, in conjunction with the recurrensts, to the arytenoidei. They are also, according to Von Ziemssen, the motor nerves of the depressors of the epiglottis. The consequences of their paralysis would therefore be, anæsthesia of the larynx, inability to depress the epiglottis, and inability also to make the vocal cords tense. The symptoms would be some degree of hoarseness of voice, with incapability of uttering high notes; and, in consequence of the association of loss of sensation with failure of the epiglottis to descend, tendency for food to enter the rima glottidis, but without the immediate spasmodic choking which naturally attends that accident. Under laryngoscopic examination, we should expect to see perfect execution of the movements of adduction and abduction.

b. *Paralysis of one superior laryngeal* may result from the implication of the nerve in various morbid processes. The symptoms would be of the

same nature as those observed in the double affection, but less pronounced, and of course the anæsthesia would be limited to one side.

2. *Paralysis of the recurrent laryngeals.* a. *Bilateral paralysis* may be due either to central or to peripheral causes. The recurrent nerves supply all the intrinsic muscles of the larynx, with the exceptions previously specified. There is, therefore, in this affection loss of power mainly in the muscles which open and close the glottis. Under the laryngoscope, consequently, the cords will be found to lie nearly motionless in the cadaveric position, that is, midway between their position in complete closure of the glottis and that which they occupy in quiet respiration. The symptoms of the disease are: complete aphonia, with undue expenditure of breath during forcible expiration, as when the patient attempts to phonate or coughs; and inability to cough or expectorate with vigour. There is absence of dyspnœa, at any rate during quiet breathing.

It is an interesting fact, as has been shown by Dr. George Johnson, that diseases involving one vagus in the neck occasionally cause paralysis of both recurrent laryngeals, the paralysis of the recurrent on the opposite side being due apparently to the transmission of morbid change or functional disturbance along the afferent fibres of the affected vagus to its nucleus in the medulla, and thence downwards along the opposite nerve.

b. *Paralysis of one of the recurrent laryngeals* is referrible either to central causes, or to intra-thoracic disease, or to tumours occupying the lower part of the neck, especially to aneurysm, to carcinoma of the œsophagus, or to enlargement of the thyroid body. It is an affection of tolerable frequency and of great significance. The affected vocal cord usually remains motionless in the cadaveric position, while the opposite healthy cord tends during phonation to pass beyond the median line, and thus to render the rima glottidis oblique. The voice loses its clearness and purity, and tends to break into a falsetto when the patient tries to speak loud. It is generally held that one of the consequences of this form of paralysis is the occurrence from time to time of spasmodic attacks of intense difficulty of breathing and cough, which are apt to prove fatal. This, however, we believe to be an error, and are ourselves disposed to refer the dyspnœal attacks which are so common in these cases to concurrent compression of the trachea, which is often induced by the same affection that induces the paralysis.

It is important to observe here that, as has been well shown and explained by Dr. Semon, whenever the recurrent nerve is the seat of organic disease, whether this be intrinsic or due to extension from without, the posterior crico-arytenoid muscle becomes affected, and that not only does this muscle suffer first, but it may suffer alone, and is the last to recover. Hence it happens that early as well as late in such disease the vocal cord, instead of presenting the usual cadaveric position, may remain fixed in the median line, that the voice consequently may not be impaired, and that without the aid of the laryngoscope the presence of the paralysis may readily be overlooked.

3. *Paralysis of the pneumogastric nerve* (that is, palsy involving loss of sensation as well as loss of motion on the affected side) has been observed in the case of tumours involving the nucleus of origin of the nerve in the medulla oblongata, and may be induced by the accidental division of its trunk in the neck, or its implication in the progress of morbid growths, at any point above the giving off of the laryngeal branches. When the nucleus of the nerve is involved in disease, there will, in addition to the laryngeal affection, be motor paralysis of the tongue and soft palate on the same side. When the nerve-trunk is involved anywhere between its apparent origin and the lower border of its trunk ganglion the tongue will escape, but there will still be paralysis of the soft palate. In other cases the existence of some lesion on the corresponding side of the neck will probably explain the nature of the laryngeal affection. The symptoms of laryngeal paralysis due to affection of the vagus are almost identical with those of paralysis of the recurrent laryngeal. Anæsthesia would probably be overlooked, unless attention were specially directed to the possibility of its presence.

4. *Paralysis of one or both of the posterior crico-arytenoidei* is not uncommon. It is apt to occur in connection with locomotor ataxy and bulbar paralysis, and hence, like ophthalmoplegia, may be regarded as one of the incidents of these affections. These muscles open the glottis; and the consequence of their paralysis is that the adductor muscles, being unopposed, tend to transform the glottis into a narrow chink, which narrows itself still further during inspiration. The essential symptoms of the affection are the gradual development of a purely inspiratory dyspnoea, generally without catarrh or disturbance of voice. At first the inspiratory stridor comes on only when some unusual bodily exertion is being made; but it gradually becomes permanent, even when the patient is at complete rest. It is especially obvious when he is asleep. At the same time expiration is performed without difficulty, and the voice remains clear. The disease is with few exceptions chronic, and rarely if ever curable. Tracheotomy is almost always needed ultimately.

5. *Paralysis of the lateral crico-arytenoidei (adductors)* is almost always combined with a similar affection of the tensors; and this combination constitutes the special laryngeal lesion of hysteria. The vocal cords remain wide apart; there is absolute aphonia and undue expenditure of air in speaking and coughing.

6. *Paralysis of the arytenoideus*.—This muscle draws the arytenoid cartilages together. When, therefore, it is paralysed, the part of the rima glottidis bounded by the arytenoid cartilages remains open during phonation, forming a triangular chink; while the vocal cords in the anterior two-thirds come into absolute contact. The result is that unvocalised air escapes through the chink when the patient speaks loud, and the quality of the voice becomes impaired or hoarse. There may even be complete aphonia. This affection is usually the consequence of acute catarrh, but is rare.

7. *Paralysis of the thyro-arytenoidei*.—These are more commonly

affected than any of the other muscles of the larynx, in catarrh, and over-exertion in speaking or singing. Their paralysis is indicated by loss of tension in the vocal cords, so that when they are brought into apposition an oval slit is still left between them. The symptoms are hoarseness and impurity of voice.

*Treatment.*—In the treatment of functional paralysis, the general health of the patient must be carefully considered, and as far as possible improved. But local treatment is especially important. For this purpose counter-irritation externally, and stimulating applications to the mucous membrane, are often useful. No local measures are so generally efficacious as the application of galvanism. This may be effected by placing the electrodes on either side of the exterior of the larynx, or (with the aid of Dr. Mackenzie's or some other suitable apparatus) one in the inter-arytenoid fold and one in contact with the skin over the situation of the thyroid cartilage. The treatment of other forms of paralysis is involved in that of the conditions which give rise to them. They are often incurable.

---

## XIX. SPASM OF THE LARYNX AND TRACHEA

1. *Larynx.*—Spasm is chiefly known as causing closure of the rima glottidis. It is rarely an independent affection, but is of common occurrence as a complication of other disorders. It is an essential element in whooping-cough, spasmodic croup, and the true epileptic seizure; it is readily induced by the inhalation of irritating vapours, or the entrance of solid or fluid matters into the larynx; and it is frequently associated with inflammatory affections of the larynx. It may also be a phase of hysteria, simulating in its symptoms those of paralysis of the abductors. Prolonged spasmodic closure of the glottis, or laryngismus stridulus (a kind of epileptic convulsion) is occasionally fatal in young children.

2. *Trachea.*—That spasmodic contraction of the trachea may take place is a physiological fact. How far it is a matter of any importance is another question. We allude to it here, however, because we believe that when aneurysmal or other tumours are compressing the trachea, and inducing from time to time spasmodic attacks of dyspnoea, the immediate cause of difficulty of breathing is not unfrequently spasmodic contraction of the muscular tissue of the compressed portion of the trachea, associated, it may be, with hyperæmia and accumulation of mucus.

*Treatment.*—For the relief of laryngeal spasm the following measures may be serviceable:—namely, the application of leeches, counter-irritants, or hot fomentations to the upper part of the chest in front, or to the neck; or the employment of hot baths, while cold water is dashed into the face; and for internal use, emetics, sedatives, and the inhalation of chloroform. Tracheotomy may be necessary. In hysterical cases the application of galvanism is indicated.

---

XX. ASTHMA (*Spasm of the Bronchial Tubes.*)

*Definition.*—The term asthma is often applied loosely to various forms of difficulty of breathing, and, indeed, is very commonly employed to designate the dyspnœa which attends ordinary chronic bronchitis and emphysema, or cardiac disease, or that due to the pressure of tumours upon the trachea. We use the term here in its more correct and restricted sense to indicate a specific affection, characterised by the periodic recurrence of general contraction of the bronchial tubes and consequent dyspnœa.

*Causation.*—Asthma is not unfrequently inherited—asthmatic parents begetting asthmatic children. It has also been observed occasionally to have a similar relation with epilepsy and other spasmodic nervous disorders. It affects males about twice as frequently as females. It may make its first appearance at any period from birth up to extreme old age; but most commonly commences during the first ten years of life. The first outbreak is often traceable to an attack of hooping-cough, measles, or bronchitis; but in a large proportion of cases no such explanation of its origin can be discovered. When, however, patients have become asthmatic, paroxysms of dyspnœa may be excited by a wide range of conditions, which are unequally operative in different cases, and some of which are not improbably capable of originating the disease. Of these some appear to act directly, others indirectly, upon the bronchial tubes. Of the former, Dr. Hyde Salter gives a long and interesting list, which includes: the inhalation of smoke, dust, or pungent vapours; the smell of cats, dogs, horses, rabbits, or other animals; the scent of the rose, privet, or other flowers; the emanations from new-mown hay and powdered ipecacuanha; change of weather, the prevalence of particular winds, and the prevalence of fog. But the most curious and mysterious of such causes is simple change of locality. Thus, some asthmatics suffer most in a dry, some in a moist atmosphere, some at a high, some at a low elevation, some in inland localities, some by the seaside, some on one side of a street of which the opposite side is innocuous to them. But most find themselves better in London and other large towns than they are in the country; and, as a rule, a moist air is more suitable for them than a dry air, a low site better than an elevated site. Among the conditions which may be supposed to act indirectly are the ingestion of certain articles of diet (which, however, differ so much for different asthmatics that it would be useless to quote examples), distension of the stomach, constipation, diseases of the brain, and violent emotions. Dr. Salter considers that when particular articles of food cause asthmatic attacks, they act after absorption, and hence directly on the mucous membrane of the bronchial tubes.

*Symptoms and progress.*—The asthmatic paroxysm usually comes on without warning. In some cases, however, it is preceded for a shorter or longer time by premonitory symptoms, which are different for different

cases, but mostly uniform for each case. These are, sometimes abnormal buoyancy of spirits, sometimes mental depression, sometimes drowsiness, but most frequently a slight degree of the asthmatic state, manifesting itself by tendency to wheeze, constriction across the chest, sense of flatulence, alteration of carriage, and the like. Among the occasional earlier phenomena of asthma are a tendency to pass an abundance of pale limpid urine, and (as Dr. Salter points out) a peculiar troublesome itching under the chin, not relieved by scratching.

The attack may come on at any hour, but is almost always uniform, or nearly so, as to the time of its supervention in each case. It sometimes occurs an hour or two after dinner, sometimes as soon as the patient lies down in bed, but in the great majority of cases between two and four o'clock in the morning, probably after the patient has had a comfortable sleep. There is no doubt (as Dr. Salter observes) that the forenoon is in every respect the most favourable time for asthmatics; their attacks least frequently commence then, and when on them are apt at that time to undergo some remission.

The symptoms of the asthmatic paroxysm are mainly those of intense dyspnœa. The patient is probably roused from sleep with the symptoms full upon him; or else, after a certain time of discomfort passed between sleeping and waking in battling with his augmenting dyspnœa, wakes to the full consciousness of his condition. He is then compelled to rise from his bed (baring his chest and throwing aside everything that hampers his respiratory movements) in all the agony of impending suffocation. The phenomena of the fully developed paroxysm are, for the most part, as follows:—The sense of suffocation is terrible; the patient's whole energies are devoted to the performance of the respiratory acts; his breathing is not rapid—often, indeed, slower than natural; but it is effected with the most violent efforts; his mouth is open, his nostrils dilated, his shoulders elevated, his head thrown back; the respiratory muscles harden and stand out, and he places himself in some constrained position which gives them leverage—standing or sitting with his elbows resting on the table or some other elevated ledge and his head buried in his hands, or grasping some unyielding object, generally above his head; he places himself even in the depth of winter at the open window. The expression of his face is one of intense anxiety; the lines are strongly pronounced; his eyes are congested and protruding, his surface pale and ghastly, or livid; copious perspirations break out upon his face, head, and trunk, while his arms and legs, and especially his hands and feet, become cold; the pulse is rapid, small, feeble and sometimes irregular. The dyspnœa is peculiar; inspiration is comparatively short, expiration greatly prolonged, and both are attended with loud wheezing; no interval exists between expiration and the following inspiration. The chest-cavity is greatly expanded; it is large and rounded from elevation of the ribs, elongated from depression of the diaphragm; and this expansion is maintained even at the end of expiration—the fact being that the chest is abnormally distended with air, and that the powerful action of the re-

spiratory muscles effects very little movement in its parietes, and consequently very little interchange of air. Dr. Salter points out that this over-distension of the chest begins to take place even before the appearance of manifest dyspnoæal symptoms, and that the descent of the diaphragm even at this early stage causes measurable enlargement of the upper region of the abdomen, which may easily be, and often is, mistaken for abdominal flatulence. On percussion the chest is probably abnormally resonant, and the cardiac dullness is diminished in area or effaced. On auscultation there is usually total absence of normal respiratory murmur, but in its place general sibilant rhonchus in all its varieties. The patient speaks with difficulty, bringing his words out pantingly one by one. There is usually no cough, at all events none at the beginning of the attack.

The duration of the paroxysm varies from a few minutes to several weeks—most frequently it is two or three days; or it commences at the usual time and subsides in the course of the following day. When the attack is much prolonged, it is generally made up of a series of shorter attacks, separated from one another by periods of more or less perfect remission. Its disappearance is attended with the gradual subsidence of the asthmatic phenomena, and the supervention of cough. This is at first dry; but by degrees crepitation replaces wheezing, and the cough is then accompanied by the expectoration of mucus in small transparent pearly pellets, and occasionally by sputa slightly streaked with blood. Frequently, and this is especially the case after short attacks, recovery is rapid and complete. In other cases, the patient suffers subsequently for a longer or shorter time from tightness at the chest and dyspnoea, with cough and expectoration.

Asthmatic attacks have a tendency not only to recur, but in a large number of cases to a distinct periodicity of recurrence. Thus in some instances they come on weekly, monthly, yearly, or at other intervals which the patient's experience enables him to foretell. In most cases, however, their recurrence is due to the more or less regular recurrence of those extrinsic causes which determine the attack: such, for example, as the assumption of the recumbent posture, variations in diet, change of residence, and change of season.

The prognosis of asthma is very uncertain. In many cases, especially if it commence in infancy, it disappears during the period of adult life. When it comes on at an advanced age it is probably permanent. Indeed, in a large proportion of cases, whatever the time of its commencement, its duration is lifelong. But then the affection usually undergoes some change of type with the advance of years. This depends in great measure on the slow supervention of organic lesions. Thus, especially if the attacks be frequent and severe, the lungs are apt after a time to become emphysematous, and the right side of the heart hypertrophous—conditions usually attended with diminution in the severity of the actual attacks of asthma, but with the development of permanent shortness of breath during the intervals between them, and other symptoms of emphy-

sema and chronic bronchitis. Further, asthmatic patients frequently acquire an almost characteristic physical conformation. They are, as a rule, emaciated, with thin, furrowed cheeks, high shoulders, body bent forwards, head thrown back, and misshapen chest—the upper part being dilated, the lower compressed, especially in the lateral direction.

Dr. Salter divides asthma into idiopathic or primary, and symptomatic or secondary. The former is the affection which we have endeavoured to describe. But symptoms identical in the main with those of asthma supervene secondarily on other affections, especially dyspepsia, catarrhal affections of the respiratory passages or bronchitis, and heart-disease, and are termed by him peptic, bronchitic, and cardiac respectively.

*Pathology.*—The extreme rarity with which death takes place in uncomplicated asthma renders the investigation of the pathology of the disease difficult. There is ample proof, however, that it occurs independently of organic lesions of the lungs, heart, or other important organs. Indeed, the observations of Drs. Gairdner and Salter seem to show that its symptoms are essentially dependent on spasmodic contraction of the muscular tissue of the bronchial tubes, and consequent narrowing of their calibre. It is easy to see that such contraction is ample to explain not only the dyspnoeal symptoms, but the auscultatory peculiarities, the sudden accession and sudden subsidence of each attack, and even the organic changes which in some cases ensue. At the same time there is something in the persistence and singular periodicity of the disease, and in the fact of the frequent dependence of the paroxysm on a variety of apparently trivial conditions, to remind us of the skin-affections known as urticaria evanida and factitious urticaria; and swelling of the mucous membrane might equally explain the temporary contraction of the bronchial tubes. Under any view, however, the bronchial affection must be referred to the operation of the nervous system, possibly excited by reflection from the bronchial surface.

*Treatment.*—In the treatment of the asthmatic paroxysm all ligatures and other impediments to respiration should be loosened, and the patient should be made to assume such a position as will enable him to use his respiratory muscles to advantage. Further, any gastric or other derangement under which he may be suffering, or any condition which may be supposed to have induced or favoured the attack should, as far as possible, be at once remedied or removed. Many drugs are beneficial. Among these may be enumerated tartar emetic and ipecacuanha in emetic doses; tobacco, given so as to produce its characteristic depressing effects, or smoked in the usual way; lobelia inflata also so given, in large and frequently repeated doses, as to cause great depression; datura stramonium or datura tatula, used either by inhalation or in the form of tincture or extract; belladonna, conium, hyoscyamus, and opium (the last, according to Dr. Salter, is injurious in uncomplicated asthma, benefiting those cases only in which there is associated bronchitis); alcohol, ether, strong coffee; nitre paper burnt in the apartment; and chloroform. The effects of chloroform are marvellous, but unfortunately they are for the most part only temporary.

The principles by which the general treatment of an asthmatic patient should be regulated are sufficiently simple : they consist in the avoidance of all the causes which in his case are known to induce an attack ; the selection of that locality for residence which experience has shown to be most suitable for his case ; and the maintenance of his general health by wholesome food, and the adoption of habits and an employment compatible with health. If the patient have not yet learnt by experience what he can do and what he cannot do with impunity, the rules which we lay down for his guidance must be such as are in accordance with what we know of the general peculiarities of the disease.

---

## XXI. HAY-ASTHMA (*Hay-fever*)

*Definition.*—This term has been applied to a peculiar catarrhal affection coming on in this country during the months of May, June, and July, and commonly referred to the emanations from various flowering grasses, or new-mown hay.

*Causation.*—A small number of persons only are susceptible, but these suffer annually at the season specified, unless they take precautions against the inhalation of the irritating influence, by either remaining indoors, betaking themselves to some large town, removing to the seaside, or taking a sea voyage. The tendency to hay-asthma seems hereditary. Conditions closely resembling it are produced in some persons by the smell of ipecacuanha or other vegetable effluvia, or by emanations from various animals, such as cats, rabbits, and dogs. The precise cause of hay-asthma has been a matter of discussion. Helmholtz, a few years ago, discovering, in the mucus discharged from the irritated mucous membrane, lowly vegetable organisms, attributed the disease to their influence. Dr. Elliotson, many years since, suggested pollen as its cause. And Mr. Blackley, himself a sufferer, has published a work on hay-asthma, in which, by a series of careful researches, he appears to have proved the accuracy of Dr. Elliotson's suggestion. He comes to the conclusion that the effects of pollen are partly mechanical, partly chemical, and that it acts locally : if applied to the eye causing conjunctivitis ; if to the nose coryza ; if by inhalation to the bronchial tubes asthmatic symptoms.

*Symptoms and progress.*—The symptoms of hay-asthma are in the main those of violent catarrh :—namely, itching, congestion, and swelling of the conjunctivæ and eyelids, and watering of the eyes ; itching, congestion, tumefaction, and copious discharge from the nostrils, attended with much sneezing ; great irritation in the throat, fauces, and soft palate ; tightness at the chest, and dyspnœa, with cough and expectoration. The symptoms vary in their severity, and generally become aggravated towards the middle and end of June. In the first instance, and in mild attacks, the conjunctival and nasal mucous surfaces alone may

suffer. The symptoms are in all cases liable to more or less regular exacerbations.

*Treatment.*—The most obvious and effectual method of treatment is the avoidance of the cause of the disease ; and, indeed, many sufferers have learnt by bitter experience entirely to shun the country and all proximity to grass fields and new-mown hay during the dangerous season. For those who are compelled to expose themselves, the use of a respirator, made, as Mr. Blackley suggests, with six or eight folds of crape or a double fold of cambric, will prove of considerable advantage. Helmholtz has recommended (and his recommendation appears to have been followed with some advantage) the washing out of the nostrils and throat with a weak solution of quinine, by means of a pipette, or nose-douche. Other remedies which have been tried with reputed success are the tincture of nux vomica in ten-minim doses, tincture of aconite, liquor arsenicalis, hydrocyanic acid, and the smoking of tobacco or stramonium.

## CHAP. IV.—DISEASES OF THE VASCULAR ORGANS

THE vascular system comprises the heart, arteries, veins, and capillaries; the lymphatic glands and vessels, together with certain ductless glands; and the blood with its tributary fluids. Of all the parts here enumerated the heart, the centre and presiding genius of the system, is by far the most important, both physiologically and on pathological grounds; and to the morbid conditions of the heart, therefore, we shall first direct attention.

### SECTION I.—DISEASES OF THE HEART

#### I. INTRODUCTORY REMARKS

##### *A. Anatomy and Anatomical Relations of the Heart*

1. *Dimensions of the heart.*—The heart has been estimated somewhat roughly, yet not inaptly, to equal in size its owner's fist. It enlarges with the growth of the body until growth ceases, and then continues to enlarge, though slowly, during the remainder of life. Its average weight in the adult male varies between ten and eleven ounces; in the adult female it is about nine ounces. The capacities of its several cavities are probably nearly equal; the auricles, however, are believed to be somewhat less capacious than the ventricles, and the left cavities than the right. The ventricles of the adult heart have, each, a capacity which has been variously estimated at from two to five ounces. The mean capacity is probably three ounces. The thickness of the cardiac walls presents considerable differences: those of the right auricle measure on the average about a line; those of the left auricle about a line and a half; those of the right ventricle (at the base, where they are thickest) very nearly two lines; and those of the left ventricle (midway between the base and apex, where their thickness is greatest) rather more than five lines. Of the cardiac orifices the auriculo-ventricular are larger than the arterial, and those of the right side larger than those of the left side to which they respectively correspond. The following table gives Dr. Peacock's circumferential measurements:—

		MALES	FEMALES
		Inches	Inches
Auriculo-ventricular	{ Right . . .	4·74	4·56
	{ Left . . .	4·	3·99
Arterial . . .	{ Pulmonic . .	3·55	3·49
	{ Aortic . . .	3·15	3·02

2. *Relations of heart to pericardium.*—The heart, which occupies the

middle mediastinum, is contained within the fibrous pericardium—a somewhat conical bag, of which the base corresponds to a portion of the central tendon of the diaphragm, the apex to the ascending arch of the aorta, the pulmonary artery and superior cava; with the parietes of which vessels, as also with those of the pulmonary veins and inferior cava, its fibrous tissue blends. The serous pericardium, on the one hand, lines the fibrous pericardium in its whole extent; on the other hand, closely invests the heart, forms a tubular sheath around the trunk of the pulmonary artery and the ascending aorta, furnishes incomplete investments to the proximal extremities of the pulmonary veins and *venæ cavæ*, and is reflected thence to become continuous with the parietal lamina. The pericardial cavity extends from the upper margin of the second costal cartilage above (at which point the ascending arch ends) to the central tendon of the diaphragm below.

3. *Relations of heart to chest-walls and surrounding organs.*—The heart occupies an oblique position. Its base, which includes the points

FIG. 47.—Diagram showing relations of heart and large vessels to front of chest.  
*a*, Centre of pulmonic orifice; *b*, Centre of aortic orifice; *c*, Centre of mitral orifice; *d*, Centre of tricuspid orifice.

of attachment of all the large arteries and veins, and is formed mainly by the auricles, is directed upwards, backwards, and to the right, and extends vertically, from the fourth to the eighth dorsal vertebra. Its apex points in the opposite direction, namely downwards, forwards, and to the left, and usually impinges between the fifth and sixth costal cartilages, a little internal to a line drawn vertically through the nipple.

The position of the apex varies, however, a little in different healthy persons, and differs a little also with change of posture, and with the respiratory movements. If it beats in the fifth interspace during recumbency, it probably beats against the sixth cartilage when the upright position is assumed. The anterior aspect of the heart, which also faces upwards, is formed below and to the right by the right auricular appendage and right ventricle; above and to the left by the left auricular appendage and left ventricle. The greater part of this aspect, however, is constituted by the right ventricle. The posterior aspect, which is also directed downwards, and rests mainly on the diaphragm, consists exclusively of the two ventricles—the left ventricle forming by far its larger proportion. About two-

thirds of the heart are situated to the left of the mesial plane of the body, the remainder to the right.

The relations of the heart and great vessels to the surface of the chest are important. The outer margin of the left ventricle extends from the left second intercostal space (midway between the osseous ribs and sternum) outwards and downwards to the apex in the left fifth inter-space. The outer margin of the right ventricle commences at the sternal end of the right fifth costal cartilage, and passes thence downwards and to the left to meet the former line in the apex.

The left auricular appendage slightly overlaps the upper edge of the left ventricle, making its appearance in the lower part of the second intercostal space. The right auricular appendage extends from about the same level above (commencing, however, at the mesial line of the sternum) downwards to the point at which the margin of the right ventricle begins. Be-

FIG. 48.—Diagram showing relations of heart and large vessels to back of chest.

tween these points it presents a semilunar form—the one limiting line taking a nearly straight course beneath the sternum, the other limiting line being convex, and extending in the third and fourth interspaces halfway from the sternum to the osseous ribs.

Of the valves, the pulmonic is the highest and most superficial; it is situated immediately to the left of the sternum (perhaps a little beneath it) in the second interspace; the aortic, which is deeper-seated than the pulmonic, and indeed partly overlapped by it, is subjacent to the junction of the left third cartilage with the sternum and to the adjoining half of the sternum; the tricuspid lies beneath the sternum, its centre midway between the sternal ends of the fourth costal cartilages; the mitral, which lies deepest of all the valves, is situated behind the pulmonic and aortic, and on a lower level than they, its central point probably corresponding to the left third interspace, a little external to the sternum.

A small portion only of the heart is in actual contact with the anterior walls of the chest, the remainder being separated from them by the thin edges of the lungs. In ordinary tranquil inspiration the lungs almost meet in the mesial line of the sternum from above down to a point midway between the sternal ends of the fourth costal cartilages. From this point the edge of the right lung still continues vertically

downwards, while that of the left retreats to the junction of the left fifth cartilage and rib, where it forms a notch just before its termination in the basal edge. A triangular interval is thus produced, situated wholly to the left of the mesial line of the sternum, bounded on either side by the edges of the lungs, and below by the diaphragm, to which the left lobe of the liver is immediately subjacent. In the outer angle of this space a small portion of the apex of the left ventricle becomes superficial, the rest of the triangle being occupied by the right ventricle.

Laterally, the heart is bounded by the lungs, from each of which it is separated by both pleura and pericardium; behind, it is limited by the posterior mediastinum, with the roots of the lungs above, and the œsophagus and thoracic aorta in its whole extent, separating it from the vertebræ; below, it lies on the diaphragm, which divides it from the liver, and partly, to the extreme left, from the stomach. Above, it is continued into the large vessels, namely, the pulmonary artery, aorta, and vena cava.

The ascending aortic arch, covered at first by the pulmonary arterial trunk, and then by the right auricular appendage, passes upwards and to the right beneath the sternum, and extends for about a quarter of an inch beyond the edge of the sternum into the right second and first intercostal spaces. The superior cava extends half an inch farther in the same direction. The transverse arch corresponds as nearly as possible to the lower half of the manubrium. The pulmonary artery passes between the two auricular appendages upwards, backwards, and to the left, and having crossed the commencement of the aorta, lies to the left of that vessel, becoming superficial at the inner part of the left second interspace, just before it retreats under the aortic arch to divide into its two branches.

### B. *Physiology of the Heart*

1. *Action of heart.*—The function of the heart is to maintain the circulation of the blood in both the systemic and the pulmonary vessels. To effect this it undergoes a series of alternately active and passive movements, which are rhythmical and follow one another with greater or less rapidity. To commence with the ventricular contraction:—The ventricles, already distended with the blood transmitted to them from their respective auricles, contract suddenly and actively, propelling their contents into the aorta and pulmonary artery respectively, and causing at the same time the closure of the auriculo-ventricular valves. Whilst this contraction is in progress the auricles, which were contracted at the moment of its commencement, gradually dilate, and by the time the ventricles have got completely empty have attained their full dimensions and are full of blood. The contracted ventricles now relax and in their turn expand, the arterial valves close, and the auriculo-ventricular valves open and allow of the flow of blood through the still dilated auricles into the ventricles. Soon the passively dilating ventricles are almost filled, when suddenly the hitherto torpid auricles contract, adding their contents to those of the ventricles, which thus become distended. Immediately after the contraction of the auricles, and indeed almost by a con-

tinuous peristaltic action, the contraction of the ventricles takes place, and the cycle of events above described recurs.

Dr. Paul Chapman has shown, that the duration of the ventricular systole diminishes in length progressively with the increase of frequency of the cardiac beats; that when the beats are 50 in the minute the cardiac systole occupies about one-third of a second; when they reach 130 a minute its duration is about one-fifth of a second.

It is important to note, in the first place, that the actions of the two sides of the heart are, as nearly as possible, synchronous; and in the second that the closure of the auriculo-ventricular valves takes place at the beginning of the cardiac systole, that of the arterial valves at the beginning of the cardiac diastole. It should be observed, too, that the force with which the ventricles act is always exactly equal to the resistance which they overcome; that (other things being equal) contraction of the arterioles calls for increase of cardiac exertion, their dilatation for its diminution; and that (again other things being equal) increased quickness of the ventricular systole implies augmented exercise of cardiac force, and conversely.

The contraction of the heart is attended with distinct pulsation in the præcordial region. The area over which this extends varies somewhat with the form of the chest, and considerably with different degrees of thinness or plumpness of the thoracic parietes. Generally it is limited to the apex, where it is always most intense, and covers not more than a square inch of surface. A certain amount of epigastric pulsation, due to the movements of the right ventricle, is compatible with health.

FIG. 49.—CARDIOGRAPHIC TRACING OF CARDIAC IMPULSE. (P. CHAPMAN.)

The space marked *a* corresponds to the duration of the auricular systole; that marked *b* to the duration of the ventricular systole from the exact beginning to the end of contraction; that marked *c* to the fall of the lever ensuing on the cessation of contraction, the notch below being due to the mechanical effect of the fall; that marked *d* shows a gradual rise, probably due to the filling of the ventricle previous to the auricular contraction. Dr. Roy has shown that the commencement of the sudden fall at the end of *b* corresponds to the cessation of contraction of the muscular substance of the heart. The base line represents the vibrations of a tuning-fork vibrating a hundred times per second.

**2. Sounds of heart.**—The contraction and the dilatation of the ventricles are each attended with a characteristic sound, which marks the commencement of the act, and is followed by a short interval of silence. These constitute respectively the first and second sounds of the heart. The first, or systolic, sound varies in character in different persons; it is, however, always deeper in tone and longer in duration than the other; it is also more or less compact, beginning and ending with a

certain degree of abruptness. It is audible over the whole of the cardiac region, but is most pronounced over the apex of the left ventricle. The second, or diastolic sound, is short, perhaps half the length of the first, sharp and sometimes ringing. It is heard with greatest distinctness at the base of the heart, and more especially in the right second interspace and over the second costal cartilage immediately adjoining the sternum. The loudness of the sounds and the extent of surface over which they are respectively audible are subject to great variety.

Many causes have been assigned for the cardiac sounds. There is, however, now no doubt that the second sound is due to the sudden closure of the arterial valves which takes place at the commencement of the ventricular diastole, and little doubt that the first sound is mainly attributable to the generally less sudden closure of the auriculo-ventricular valves which attends the commencement of the ventricular systole. But it is pretty certain that the first sound is reinforced by that due to the contraction of the muscular tissue of the cardiac walls. For the most part, as has been already pointed out, the two sides of the heart act in unison; and hence the two arterial valves usually concur in the production of the second sound, the two auriculo-ventricular in that of the first; but, inasmuch as the action of the left side of the heart is far more powerful than that of the right, the valves of that side take the chief share in causing the cardiac sounds. It is owing to this fact that the second sound is usually loudest towards the base of the heart, to the right of the sternum, where the ascending aortic arch approaches the surface, and that the first is usually most obvious where the left ventricle becomes superficial, namely, at the apex. When the sides do not act in perfect unison, a more or less obvious reduplication of the cardiac sounds takes place.

3. *Pulse*.—The intermittent injection of blood from the heart into the arteries produces the phenomenon known as the pulse. The beats of the pulse correspond as a rule in number and rhythm to the contractions of the cardiac ventricles; and, like them, follow one another, for the most part, with remarkable regularity; although liable, in different persons, and under different circumstances, to present great variations as to rate and force, and always presenting slight relative increase of rate and force during inspiration, and slight relative decrease during expiration. The character of the pulse, although depending mainly upon the action of the heart, is largely modified by the condition of the arteries in which it occurs, and by that of the capillary arteries and capillaries, and of the venous system, beyond. During the whole period of the contraction of the left ventricle its contents are being propelled into the aorta; and the force which is thus exerted within the arteries is expended, partly in driving the blood already within them onwards, partly in stretching their elastic walls. The consequent arterial tension attains its maximum with more or less rapidity, and then diminishes before the systolic action is completed. As soon as, with the cessation of the systole, the propulsion of blood into the aorta ceases, the distended

arteries contract upon the blood within them, still propelling it onwards, but with gradually diminishing force, until they have attained their former calibre or until their contraction is interrupted by the next cardiac systole. The period here adverted to corresponds to the ventricular diastole. If the pulse presented no other elements than those immediately due to the phenomena just considered (namely, the systolic distension of the artery on the one hand, and its

FIG. 50.

diastolic collapse on the other), the sphygmographic trace of the pulse would have some such form as that represented in fig. 50.

There would be a sudden rise, presenting a rounded summit, the highest point of which would correspond to the moment of highest arterial tension; and this would be followed by a gradual fall. But for the most part the sphygmographic tracing displays other elements besides these. In the first place the line of ascent is usually prolonged vertically upwards and then suddenly falls, forming a very acute angle, before it merges in the convex summit above indicated; and in the second place the line of diastolic collapse is for the most part interrupted at its commencement by a more or less distinct rise, and frequently after a short interval by a further and less distinctly marked wave, or a diminishing series of waves. The typically complete tracing would thus present not less than four successive waves, of which at least two would correspond to the systole of the heart, and at least two to the diastole. The first of these waves, which is known as the *primary* or *percussion wave*, is generally attributed, not to any actual addition to the quantity of blood which the artery presenting it already contains, but to the impulse which is supposed to be transmitted along that blood by the shock of the commencing systole; and is supposed to precede by a scarcely appreciable interval the *secondary* or *tidal wave* which follows it. Dr. Galabin, however, shows that this explanation is incorrect, and 'that the percussion and tidal waves form in the artery but one wave, and are only separated by the sphygmograph. Owing,' he says, 'to the inertia of the long lever it is carried up a little too high, and when in falling it meets the true arterial wave it is again tossed up, and thus forms the tidal wave.' The third, or the *dicrotic wave*, has, like the first, been variously explained. It has

FIG. 51.—a, Primary or percussion wave; b, secondary or tidal wave; c, dicrotic wave; d, fourth wave; e, aortic notch; f g, duration of cardiac systole; g h, duration of cardiac diastole.

The dotted line represents the tracing which would be drawn if the instrument followed the movement of the artery with perfect accuracy. Copied, with slight modification, from Dr. Galabin's diagram.—*Thesis for the Degree of M.D. Cantab.*, 1873.

been attributed by many to the shock of the sudden closure of the aortic valves, an opinion in which Dr. Galabin concurs; and again to

the recoil of the hitherto distended arteries. But the cause is probably that which Dr. Sanderson assigns for it. He points out that as the wave due to the injection of the ventricular contents into the aorta takes a certain time to reach the capillary arteries, and as hence the period of greatest movement in the latter vessels must take place distinctly later than that in the aorta, so the subsidence of this wave and the period of comparative rest which marks the end of systole and the whole of diastole is likewise delayed in transmission to the peripheral vessels; and that consequently there is a moment at which, while the blood is almost stagnant in the aorta, it is still flowing rapidly through the minuter vessels, and a later moment at which the blood in the capillaries also becomes comparatively quiescent. But this arrest in the capillaries, accompanied as it is by the contraction of the elastic arterial coat upon the diminished contents of the vessels, produces a virtual distension and a sudden increase of pressure throughout the arterial system. The dicrotic wave is the expression of this arterial tension. The fourth wave has probably, as Dr. Galabin considers, the same relation to the dicrotic wave as the tidal to the percussion wave.

Let us now briefly consider the significance in the order of their occurrence of the more important of the several factors of the pulse-tracing which have been enumerated. The initial rise will necessarily be largely determined as to its amplitude by the suddenness and violence of the cardiac systole; but will obviously be also influenced more or less considerably by the condition of the arteries—flaccidity aiding it, tension, on the other hand, opposing it. The presence of the tidal wave as a distinct event depends mainly upon the duration of the tension of the arteries due to the ventricular systole. If the tension be of short duration the percussion wave falls rapidly and continuously until its fall is arrested by the dicrotic rise; if it be long-sustained, then the second rise becomes developed, varying in its form according to the condition of the artery. The breadth of the combined summits of these two curves is, therefore, a measure of the duration of the tension here adverted to; the breadth of their bases, as determined by a horizontal line drawn from the commencement of the systolic rise to the end of the systolic fall, is a measure of the duration of the cardiac systole; and the lowest point of the notch which separates the tidal from the dicrotic wave indicates the moment of closure of the aortic valve. The third rise (the dicrotic wave) may be regarded as a measure of the completeness of the check which the systolic wave experiences in the smaller vessels during the diastolic period, and is indicative, therefore, either of comparative feebleness of the heart's action or of high tension of the venous relatively to that of the arterial system. The duration of the diastolic period is measured by the horizontal line which may be drawn from the aortic notch to the commencement of the next systolic ascent.

The character of the pulse varies in health, not only in different individuals, but in the same person at different times and under different circumstances. It may be *frequent* or *unfrequent*, conditions which may

be recognised as well by the finger and the watch as by any more complicated machinery. It may be *long* or *short*. These terms apply, not to the whole interval between the commencement of one pulsation and that of the pulsation which next follows (for in that case they would be synonymous with 'unfrequent' and 'frequent' respectively), but to the duration of the systolic wave. These qualities may be roughly recognised by the finger, but are demonstrated with accuracy only by the sphygmographic tracing. It should be noted here that when a pulse becomes increased in frequency, this increase is due mainly to curtailment of the diastolic period. It may be *large* or *small*. These terms are employed somewhat loosely; the former should perhaps be used of that state in which a considerable volume of blood is propelled into the arteries at each systole, and the latter of the converse condition. We are apt, however, to term that also a large pulse which occurs in dilated arteries, such as those of elderly persons, and that a small pulse in which the arteries are simply contracted. These different forms of largeness or smallness are often combined, and are indicated respectively in the sphygmographic trace by relative amplitude of the systolic waves. The pulse may be *strong* or *weak*, or in other words *hard* or *soft*. The former resists compression by the finger, the latter is easily obliterated by it. The best test, however, of strength of pulse is again the sphygmograph, by means of which the amount of pressure necessary to procure obliteration can be estimated with some degree of accuracy. When there is high arterial tension it is necessary to use considerable pressure in order thoroughly to develop the characteristic tracing.

### C. Pathology of the Heart

The heart and structures associated with it may, as is the case with all other organs, become the seat of inflammatory or other processes, which will produce all the local and general symptoms commonly belonging to such processes. But the heart is an instrument of extreme delicacy, and is liable, under the influence of these and other conditions, to have its mechanism more or less seriously deranged. Its derangements, which may be structural or functional, or both combined, cause various local and remote or general consequences which are the characteristic symptoms or sequelæ of heart disease. We propose, in addition to making some remarks on the physical examination of the heart and structures associated with it, to consider these derangements and their consequences briefly, apart from the intimate nature of the pathological lesions from which they spring, and apart also from the special symptoms due to the specific nature of these lesions.

#### 1. Physical Examination

a. *By inspection* we may often determine facts of primary importance in relation to cardiac diseases. When effusion of fluid has taken place into the pericardium, when there are intra-thoracic growths involving

this membrane or its vicinity, or when the heart is much enlarged, especially in the case of children and persons with yielding ribs, the præcordial region is often manifestly protuberant. Under similar circumstances the intercostal spaces are sometimes effaced, and the ordinary respiratory movements diminished or annulled. The situation and character of the apex-beat can generally be readily determined by inspection. In hypertrophy and dilatation of the heart or of its left ventricle, it is carried downwards and outwards; in hypertrophy and dilatation of the right ventricle, it is carried outwards; and always, when from any cause the heart is displaced, the situation of the apex-beat is displaced also. Inspection will also show whether the apex-beat is powerful and heaving, as it is in hypertrophy of the left ventricle, or diffused, as it becomes when the right side mainly is enlarged. Again, under various conditions, pulsation may be observed not only over the apex, but over the surface of the ventricles, and even over the great vessels at the base. Thus, in cases of enlarged heart or of pericardial effusion, or even of displacement of the heart to one or other side, pulsation referrible to the surface of the ventricles may often be observed in addition to the ordinary apex-beat. Surface pulsations are generally alternate with the apex-beats, and due to the ventricular diastole; and, when visible on the left side of the chest, may be observed to run as a wave from the sternum along the intercostal spaces. Further, when the edges of the lungs are retracted as after deep expiration, and still more when the upper part of either lung has shrunk from old tubercular or inflammatory disease, marked pulsation, due to the large vessels and auricles, may be observed in the second and third intercostal spaces. Visible pulsation occurs also over aortic aneurysms. The pulsation of the large vessels and of aneurysms are synchronous with the apex-beats.

*b. Palpation* will assist in the determination of many of the phenomena which simple inspection also reveals. But by palpation we can recognise with greater accuracy the force and character, and the area, of pulsation; and we can further recognise the presence of unyieldingness which often attends pericardial exudations and intra-thoracic growths, and the existence of œdema, doughiness or fluctuation which may accompany pericarditis, or affections involving the parietes of the præcordial region. But above all, we can ascertain the existence of the tremors or thrills, which are often present generally over the præcordial area in cases in which the pericardial surface is rough from inflammatory lymph, and pericardial friction is to be heard; and which often occupy definite areas in various forms of endocardial lesion. Thrills occur also over aneurysms.

*c. By percussion* the area of præcordial dulness may be ascertained. As a general rule this is increased when the heart is enlarged, or the pericardium distended, or in the case of mediastinal growths intruding between the thoracic walls and the pericardium. It is diminished when the heart is unduly small, or when emphysematous or distended lungs extend beyond the proper pulmonary limits. By such means, in fact, the area of cardiac dulness may be much reduced, even when abundant peri-

cardial effusion or great enlargement of the heart is present. Sense of resistance is probably best appreciated by percussion.

*d. Auscultation* reveals the healthy and the unhealthy sounds referrible to the heart, the former of which have already been considered, the latter of which will be fully discussed farther on.

## 2. *Displacements of the Heart.*

Simple displacement of the heart is met with under many different circumstances. Occasionally, in company with the other viscera of the chest and abdomen, it is found transposed. Ascites or abdominal tumours may carry its apex upwards and to the left; aneurysms of the arch, and other tumours of the upper part of the chest and posterior mediastinum, may cause it to descend. Serous or other effusions into either pleura commonly push it over towards the opposite side; while the contraction of the lung and chest-wall which so often attends pulmonary cirrhosis and the absorption of pleuritic fluid tends to attract it more and more towards the affected side. The displacements which result from the last conditions are generally much more noticeable when they take place towards the right than when they take place towards the left; and, indeed, when the left pleura is distended it is not uncommon to find the heart beating wholly between the right nipple and right edge of the sternum. In spinal curvature also the position of the heart is often much modified, being then largely determined by the relative sizes of the two halves of the chest, and by the degree and form of the curvature; sometimes it lies wholly to the right of the sternum, sometimes beneath it. Occasionally, when the patient is markedly pigeon-breasted, the heart occupies the whole of the space which lies between the two nipples. The most remarkable displacements of the heart are those which result from the growth of intra-thoracic tumours. In such cases the apex of the organ has been found beating in the right axilla.

In reference to displacements, it may be observed that the base of the heart is closely attached to the structures occupying the posterior mediastinum, while the rest of the organ is free; and that consequently, although, no doubt, the posterior mediastinum and the base of the heart become displaced to a greater or less extent, it is the apex which chiefly suffers. It may be useful to point out that transposition of the heart and other viscera has, in association with pulmonary symptoms, led to the erroneous diagnosis of pleurisy with effusion on the left side; and that displacement of the vessels at the base of the heart in conjunction with displacement of the heart itself, or displacement of the vessels alone in dependence on the contraction of tubercular cavities of the apex of the lung, is apt to suggest the presence of an aneurysmal tumour.

## 3. *Affections of the Pericardium*

*a. Pericardial effusion.*—The effusion of fluid into the pericardial cavity is a common incident in various diseases. In general dropsy, more

or less serum is commonly poured out into this, as it is into any other, serous cavity. In ordinary inflammation a transparent opaline fluid accumulates in its sac; and in rupture of the heart or of an aneurysm at the origin of the aorta its cavity quickly becomes distended with blood.

When fluid is poured out into the pericardium it gradually distends it, enlarging it in all its dimensions, but chiefly in those situations in which its walls are least resistant. The cavity becomes rounded, and at the same time elongated, especially in the upward direction along the ascending aortic arch and pulmonary artery, and thus acquires a pyriform shape with the narrow extremity above. Moreover, by its distension it displaces the diaphragm downwards and the lungs laterally. At the same time the heart is necessarily carried with the portion of the parietal pericardium to which it is united backwards, and consequently away from the anterior thoracic walls. The quantity of fluid which accumulates is sometimes enormous. Two and even three quarts have been met with. The larger quantities are generally the result of chronic disease, which allows of the gradual distension of the cavity to a much greater extent than is possible in acute cases.

The physical signs of pericardial effusion are tolerably distinctive. Distension of the pericardium tends to cause prominence of the præcordial region, with widening and smoothing away of the intercostal spaces, which becomes more pronounced and occupies a larger area as the distension increases, and is always relatively greater in the yielding chests of young children than in the rigid chests of adults. Other facts observable by inspection are deficiency of respiratory movement over the affected region, elevation of the apex-beat (if indeed the apex-beat remains visible), and diffused pulsation chiefly noticeable in the interspaces. As the enlarging pericardium displaces the lungs more and more, so does the præcordial dulness become more and more extensive. In accordance with the form which the cavity itself assumes, the enlarging area of dulness acquires the shape of an elongated triangle, of which the acutest angle is above, the shortest side below. This area may extend up to the clavicle, and be bounded to the left by an oblique line passing from the junction of the left first rib and cartilage downwards and outwards through or beyond the left nipple, and to the right by a line running for the most part vertically somewhere between the right nipple and the median line of the sternum. The only influence of pericardial effusion on the cardiac sounds is to render them feeble and indistinct.

The direct effects of pericardial effusion are to embarrass the action of the heart, and hence sooner or later to cause such symptoms as usually arise in the course of valvular disease. Abundant accumulation of fluid, especially if it have taken place rapidly, tends to compress the heart, and to prevent it from expanding. Death in cardiac rupture is largely due to this mechanical influence. The distended pericardium presses upon neighbouring organs, and may thus cause obstruction to the veins which empty themselves into the heart, and difficulty in swallowing. It may also cause collapse of the left lung.

*b. Pericardial roughness and friction.*—When the surfaces of the pericardium are roughened, as they are in pericarditis from the formation of a false membrane, a *pericardial murmur* or *friction sound* may generally be heard. This varies in character: being sometimes a uniform to-and-fro sound like that produced by rubbing two pieces of paper together, sometimes a more or less uniform crackling, rumbling or creaking, sometimes a series of irregular jogs, which are generally more numerous than the sounds of the heart and seldom synchronous with them, and depend on the fact that the equable movement of the opposed surfaces on one another is interfered with by the obstacle which their roughness or stickiness interposes. Pericardial sounds, especially if of limited extent, are not always distinguishable from endocardial murmurs. They seldom, however, present much intensity, are probably never musical, and are scarcely perceptible excepting immediately over the spot at which they are developed. They are most common and most persistent over the right ventricle. Pericardial friction is usually rendered louder by the pressure of the hand or stethoscope upon the præcordial region, and during expiration, and is often attended with a marked tactile thrill. It occurs at the beginning of pericarditis when the roughened pericardial surfaces are in contact, disappears for the most part as serum accumulates and separates them, and recurs as the fluid becomes reabsorbed during convalescence.

*c. Pericardial adhesions and growths.*—After inflammation, the pericardium generally becomes adherent in a greater or less degree. The adhesions vary much in thickness and density, and not unfrequently cause serious and permanent embarrassment of the heart's action. It is sometimes important, therefore, to determine if possible whether such adhesions be present. In many cases the clinical history will decide this point for us. But in many we have no such aid to diagnosis. Unfortunately, the clinical signs of adherent pericardium are few and untrustworthy. Among those which have been regarded as significant are: persistent extension of præcordial dulness and prominence of the præcordial area; abnormal sense of resistance on percussion; permanent elevation of the apex-beat and displacement to the left; and recession of the thoracic walls over the apex of the heart, at the time of systole, in place of the normal protrusion.

The presence of pericardial growths will have much the same local influence as that of old adhesions, at any rate so far as extension of præcordial dulness is concerned. But the symptoms are more rapidly progressive; the heart is liable to undergo traceable and often considerable displacement; and there is always the likelihood of the development of obvious tumours in the thoracic parietes, above the clavicles and elsewhere.

#### 4. *Affections of the Muscular Walls and Cavities*

*a. Atrophy.*—The heart, like all other muscles, tends to shrink when the work devolving on it lessens; or when the body generally wastes. General atrophy of the organ is observed for the most part in chronic

wasting diseases, such as cancer of the cardiac orifice or pylorus, pulmonary phthisis, tubercular disease of the bowels, and diabetes; and may then become extreme. Dr. Church records the case of a middle-aged woman dying of cancer of the pylorus in whom the heart weighed only  $3\frac{1}{8}$  ozs. General wasting is now and then also observed apparently as a consequence of obliteration of the pericardium by adhesions. Partial atrophy is met with in connection with valvular lesions, and mainly in the case of mitral disease, where, in consequence of interference with the due supply of blood to the left ventricle, this has less work to do than it should have, and therefore tends to shrink. Such atrophy is probably in most cases relative; but occasionally, and especially in mitral obstruction, is actual and well-marked. The muscular tissue of simply atrophied hearts is usually darker and firmer than in health.

*b. Hypertrophy and dilatation.*—*Hypertrophy* of the heart is doubtless always the result of overwork of the organ. This overwork may be the consequence of undue resistance to the escape of blood from the heart or from any one of its cavities, of dilatation of its chambers, which diminishes their efficiency as organs for propelling the blood, of nervous palpitation or of excessive muscular exertion, or lastly of pericardial adhesions, which, by the embarrassment they cause, compel persistent increase of cardiac effort. Hypertrophy of the left ventricle tends to take place in the various forms of Bright's disease, but chiefly in connection with contracted granular kidney. It appears to be due to the impediment which there is in these affections to the passage of blood through the systemic capillary arteries, and is associated with heightened tension which prevails throughout the arterial system. It arises also from disease of the aorta and other large arteries; and is especially common as a consequence of obstructive or regurgitant aortic valve disease. Hypertrophy of the other chambers results directly from disease of the valves immediately in front of them, or from anything else which impedes the escape of blood from them. Thus hypertrophy of the right ventricle may be due either to disease of the pulmonic valves, to obstructive disease in the lungs, especially chronic bronchitis and emphysema, or to affection of the mitral orifice. Hypertrophy consequent on pericardial disease, and that arising from long-continued palpitation, are for the most part general. Dr. Allbutt believes that the hypertrophy due to violent muscular exercise begins on the right side of the heart, and is propagated thence to the left side.

*Dilatation* of the heart probably always in some degree accompanies hypertrophy, and owes its origin to similar causes. But it must be regarded, less as an evidence of strength than as a result of weakness (of the yieldingness of the heart's walls to the increased internal pressure to which they are subjected), and, although accompanying hypertrophy, as antagonistic to it. It will hence be readily understood that, other things being equal, a heart intrinsically weak will become dilated more than hypertrophied, under the stimulus of over-exertion; and that under similar circumstances a heart, intrinsically strong, will become hyper-

trophied more than dilated. It should be noted that dilatation, which is sometimes the primary change in hearts that are simply feeble, not only impairs efficiency, but actually furnishes an incentive to cardiac exertion and overgrowth.

The muscular tissue of the heart in cases of hypertrophy is for the most part firm and dense; and in some cases, indeed (as for example in the hypertrophy which attends chronic renal disease), it is supposed that the hardness and closeness of texture are due in some measure to the disproportionate increase of the connective tissue of the organ. It is important to observe, however, that occasionally when dilatation is in advance of hypertrophy, the muscular tissue is softer than natural; and that sooner or later there is a tendency in most cases for the hypertrophied tissue to degenerate, and for the heart to become weak and inefficient.

In chronic Bright's disease the heart (mainly the left ventricle) becomes hypertrophied, often to an extreme degree; but dilatation is comparatively slight. In obstructive disease at the aortic orifice, again, hypertrophy affects mainly or exclusively the left ventricle, but dilatation is more marked than in the former case. In regurgitant aortic disease dilatation of the left ventricle is always much greater in proportion than in either of the foregoing cases; the walls, however, become very thick, and, in fact, it is in this variety of cardiac disease that the heart attains its greatest bulk. It may weigh between forty and fifty ounces. In all the above cases the enlarged heart presents its normal conical form, or at any rate deviates but little from it. If, however, the left ventricle be alone or chiefly enlarged, not only does its left edge extend further than usual to the left, so that more of the ventricle is exposed when we look at the organ *in situ*, but its apex projects far beyond that of the right ventricle, and the heart becomes elongated.

In mitral disease, in chronic pulmonary affection, and in disease at the pulmonic orifice, the right ventricle enlarges, while the left undergoes but little change and possibly even shrinks. The result on the form of the heart is that it becomes globular instead of conical or elongated, and that the right ventricle either takes an equal share with the left in forming the apex of the heart, or exclusively forms the apex. Hypertrophy and dilatation of the auricles necessarily cause some modification in the form and dimensions of the base of the heart; but their effects do not call for detailed description.

*c. Signs and symptoms of atrophy.*—The physical signs of general atrophy of the heart are: diminution of the area of præcordial dulness, feebleness of the apex-beat and of the pulse, and feebleness of the cardiac sounds. But inasmuch as the atrophy is usually in some sort of proportion to concurrent atrophy of the rest of the organism, the dwindled heart still remains sufficiently strong to perform the offices required of it, and as a rule gives rise to no untoward symptoms. The atrophy of the left ventricle, which occurs in mitral disease, is related to the weakness and irregularity of pulse which characterise that lesion.

*d. Signs and symptoms of hypertrophy and dilatation.*—The physical signs of enlargement of the heart are : increase of the area of præcordial dulness, displacement of the heart's apex, and heaving powerful impulse. But the phenomena differ very much according to the relative amounts of dilatation and hypertrophy present, and according as the right or left side is chiefly affected. Simple hypertrophy tends to render the cardiac sounds, and more especially the first sound, dull and indistinct. Simple dilatation tends to make the sounds short and sharp. When, however, hypertrophy and dilatation are proportionate, and especially when dilatation is in excess of hypertrophy, as it is in regurgitant aortic valve disease, the sounds of the heart become extremely loud. When the cardiac enlargement is general or the left ventricle only is involved, the apex is carried downwards and outwards, and may even impinge in the seventh or eighth interspace ; the apex-beat, moreover, is heaving and covers a wider area than in health. When the right side is hypertrophied and dilated, the cardiac dulness is increased in its transverse diameter, the apex of the heart is thrown to the left, but probably retains its normal level, and the beat is diffused. Moreover, there is usually marked epigastric pulsation, and sometimes pulsation to the right of the sternum. In enlargement of the left side of the heart the pulse is full, strong, and prolonged. In enlargement of the right side the pulse is unaffected, but there is probably undue fulness and possibly pulsation in the larger systemic veins, especially those of the neck. Since hypertrophy and dilatation of the heart are to a large extent compensatory, their presence for a time and to a greater or less degree prevents the occurrence of symptoms which would otherwise become developed. A time, however, comes in most cases when, either the conditions causing hypertrophy and dilatation assert themselves, or the cardiac enlargement itself causes cardiac embarrassment, or degenerative changes occur in the hypertrophied muscle, and symptoms of cardiac disease, like those which attend valvular lesions, manifest themselves. In almost all cases of cardiac hypertrophy and dilatation there is valve disease or some other associated condition which largely influences the physical signs, the pulse, and the general symptoms.

### 5. Affections of the Valves

Any of the four valves of the heart may be the seat of disease. But those of the right side usually suffer during foetal life, while those of the left side are chiefly liable to be attacked after birth. Moreover, the auriculo-ventricular valves are more frequently affected than the arterial.

*a. Causes of valve disease.*—The causes of congenital valve disease are sometimes inflammation, sometimes arrested or faulty development. The causes of so-called ' acquired ' valve disease are mainly inflammation and degeneration : the former occurring, as a rule, in the earlier periods of life in connection with rheumatism and chorea, the latter coming on

for the most part with other degenerative changes as old age approaches. Syphilis, also, is a cause of valve disease in adult life.

*b. Manner of valve disease.*—The valvular mechanism may be disturbed in two ways. Either the orifice may be constricted, and the blood-stream in its normal course through it be impeded; or the cusps may close imperfectly and so allow of regurgitation. The two defects are often associated.

*Obstructive aortic or pulmonic valve disease (stenosis)* may be due to either of the following conditions:—(i.) There may be more or less adhesion of the several segments to one another. As a congenital defect, it is not uncommon to find two contiguous cusps blended as far as their corpora arantii, the coalesced sides forming a vertical frænum dividing the upper aspect of the compound organ into two halves. More rarely the three cusps are thus blended, forming between them a conical funnel with a small orifice in the apex which looks upwards. (ii.) There may be abundant inflammatory granulations. (iii.) The cusps may be thickened, irregular, and rigid from atheromatous and calcareous changes.

*Regurgitant aortic or pulmonic valve disease* may depend (i.) on contraction or puckering of the free edges of the valves, in consequence of which they fail to meet; (ii.) on ulcerative destruction or contraction of the valves at their angles, which allows the intermediate free edges to form pendulous or everted flaps; (iii.) on rupture with partial detachment, or on perforation, of the curtains (we do not refer to mere perforations in the lunulæ, which do not in any degree impair the efficiency of the valves); and (iv.) on dilatation of the arterial orifice.

*Obstructive mitral or tricuspid disease (stenosis)* may be caused in various ways. (i.) The edges of the flaps may cohere. This condition is often congenital, and generally, when the cohesion is extensive, the valve assumes a funnel-like character, with its apex pointing towards the ventricle, and presenting a narrow button-hole slit. In most cases of this kind the valve is generally thickened, the chordæ tendinæ are short and thick, and their smaller branches which radiate into the valves are apt to be blended with them and with one another. (ii.) There may be general inflammatory thickening, together with inflammatory outgrowth. (iii.) The valves may be rigid and irregular from atheromatous and calcareous deposition.

*Regurgitant mitral or tricuspid disease* may depend (i.) on mere contraction of the free edges of the cusps; (ii.) on shortening or rupture of the chordæ tendinæ; (iii.) on perforation of the valve; and (iv.) when there is dilatation of the cavities of the heart, either on associated dilatation of the auriculo-ventricular orifice, which the cusps are then unable to close, or on want of due proportion between the size of the ventricular cavity and the length of the chordæ tendinæ and muscoli papillares. The tricuspid valve is especially apt to allow of regurgitation from the last-mentioned cause.

*c. The effects of valvular disease on the walls and cavities of the heart* are important and characteristic. This subject has already been briefly considered, but we propose to discuss it now in fuller detail. Whenever there is obstructive disease at the aortic orifice, the left ventricle undergoes gradual hypertrophy, attended with more or less dilatation. For a time this enlargement is almost purely compensatory; the increased force of the cardiac contractions almost exactly counterbalances the effects of the obstacle; the heart beats regularly, the ventricle empties itself at each systole, the mitral valve acts perfectly, and the auricle experiences no difficulty in the transmission of its contents into the ventricle. So far, all the morbid changes are confined to the left ventricle. But after a longer or shorter period disproportion arises between the hypertrophy of the ventricle on the one hand, and its dilatation and the impediment to be overcome on the other; the ventricle fails to act efficiently, probably does not wholly expel its contents at each beat, and the auricle consequently begins to experience some difficulty in getting rid of its contents, and now, in its turn, becomes dilated and hypertrophic. The same sequence of phenomena follows that virtual impediment to the aortic circulation which results from aortic valve incompetence. In this case, however, dilatation doubtless precedes hypertrophy, and the auricle probably becomes stimulated to over-exertion at a comparatively early period.

Whenever disease, whether it be obstructive or regurgitant, exists at the mitral orifice, blood tends to accumulate in the left auricle, while increased force is needed for its propulsion thence; the cavity, therefore, of the auricle becomes enlarged, and its walls thickened. But inasmuch as no valves exist at the orifices of the pulmonary veins, or in any part of the course of the pulmonary vessels, the augmented pressure of blood which commences within the auricle speedily extends backwards throughout the entire pulmonary system. And hence arise, impediment to the escape of blood from the right ventricle, and its consequent hypertrophy and dilatation.

Disease affecting the pulmonic orifice, equally with increased resistance to the flow of blood along the pulmonary artery, necessarily causes dilatation and hypertrophy of the right ventricle, which are presently followed by similar affections of the right auricle.

Disease at the tricuspid orifice provokes like changes in the right auricle, and in connection therewith accumulation of blood in the systemic veins, to be remotely followed by similar conditions in the systemic capillaries and arteries, and consequent impediment to the escape of blood from the aortic orifice.

It will be understood from the foregoing remarks that when disease (actual or virtual) exists at any valvular orifice, first, the chamber behind it becomes hypertrophied and dilated, and subsequently the same conditions gradually involve chamber after chamber in the backward direction, until possibly every one thus becomes affected in a greater or less degree; and, further, that in the extension of these conditions from

the left auricle to the right ventricle, or from the right auricle to the left ventricle, the pulmonic or the systemic vascular system, as the case may be, necessarily suffers from undue accumulation and pressure of blood within it.

But while the immediate effect of valvular disease is progressive hypertrophy and dilatation of the chamber behind the implicated valve, the chamber in front (at any rate for a time) either does not enlarge, or enlarges very slightly, or even undergoes atrophy. In simple mitral obstructive disease the left ventricle usually shrinks.

The form of the heart, as we have shown, becomes largely modified by the hypertrophic and other changes above discussed.

*d. Cardiac murmurs.*—The chief physical sign of valvular disease is the presence of a murmur or bruit, occurring either during the systole or during the diastole of the ventricles, and due either to some impediment to the onward flow of blood, or to regurgitation. Cardiac murmurs either replace the normal sounds of the heart or are super-added to them. They are necessarily loudest at the points at which they are developed; but in consequence of the intervention of cardiac structures which are not implicated, or of the free edges of the lungs, they are not necessarily loudest at those portions of the chest surface which lie nearest to these points. Again they are carried, as might be supposed, by the blood-stream, and are heard louder in the course of that stream than in the opposite direction. Endocardial murmurs present a wide range of character, dependent on differences of intensity, quality and pitch. As to intensity, they may be so soft as to be barely detectable, or so loud as to be distinctly audible by the unaided ear at a short distance from the præcordial region. As to quality, they may resemble a simple whiff, a whispered vowel, a whispered *r*, or a prolonged *s*; they may be harsh and rough, or grating; or they may be distinctly musical; and the musical note may vary in pitch from bass to treble, from a deep hum or buzz to a whistle. They are often compared to familiar sounds, such as blowing, cooing, sawing, rasping and the like; and, apart from such special qualities, are usually also distinguishable from the normal heart sounds by their greater prolongation, and by their gradual subsidence or onset. Endocardial murmurs are the result of molecular vibrations produced in the blood as it traverses one or other of the cardiac orifices. Such molecular vibrations are, of course, always present, whether in health or disease; but they are only rendered sufficiently intense to evolve sound either when the blood is driven with unnatural velocity through one or other of the orifices, or when in its course it meets with some impediment, or encounters some roughness or projection or some pendulous vibratile body, or when (as in regurgitation) opposing streams meet. It is not always possible, nor is it important, to determine the conditions on which the different qualities of murmurs depend. It may, however, be remarked that roughness or hoarseness of sound implies for the most part roughness or irregularity (however produced) at the orifice at which it is developed, and that musical quality may be determined by extreme nar-

rownness of orifice, and especially by such conditions of the edges of an orifice as permit them to perform regular vibrations. The roughest and most grating murmurs probably are the consequence of partial detachment of valves or of rupture of chordæ tendineæ, which allows the implicated cusp to flutter loosely in the blood-current. The most distinctly musical murmurs are for the most part regurgitant, as might be supposed from the combination of narrowness of orifice and of vibratile edges which is then commonly present. There can be no doubt that the quality of cardiac murmurs is often very distinctly modified by the resonance of blood-containing ventricular cavities; in fact, that murmurs not otherwise musical are thus rendered musical, and that musical murmurs have some of their harmonics developed by this means with disproportionate power. It is obvious that such modifications must occur mainly while the ventricles are filling, or are full, and hence specially affect murmurs developed during the ventricular diastole. It is possible that the deep tone of so-called 'pre-systolic' murmurs is in some measure due to this

FIG. 52.—GRAPHIC REPRESENTATION OF AORTIC MURMURS.

1, 2. First and second cardiac sounds respectively. a, b. Systolic murmurs. c. Diastolic murmur.

circumstance; and that the different qualities of the same murmur, as heard in the neighbourhood of the aortic orifice where it is created, and at the apex whither it is conveyed, are similarly explicable.

*e. Differential diagnosis of cardiac murmurs.*—Leaving these general considerations, we proceed to discuss the differential diagnosis of valvular diseases by the aid of the murmurs which severally attend them.

*i. Aortic valve disease.*—*Obstructive disease* or *stenosis* is characterised by the presence of a murmur which commences with the commencement of the heart's systole, and is continued onwards during the systolic silence. Rarely it occupies the whole systolic period. It is usually loudest over the right second costal cartilage and second interspace close to the sternum, and over the right half of the sternum in the corresponding situation; it is carried along the transverse arch, across the manubrium, and is sometimes distinctly audible even in the back along the descending arch and upper part of the thoracic aorta; and it diminishes in force as it is traced from the base of the heart to the apex. The extent of its diffusion depends

largely upon its loudness or pitch; when feeble it may be heard only over the ascending arch. Its commencement is synchronous with the carotid pulse and cardiac impulse.

The murmur of *aortic regurgitation* commences with the second sound of the heart, which in some cases it entirely replaces, and is generally much prolonged, sometimes up to the very commencement of systole. It is usually most distinctly audible in the neighbourhood of the aortic orifice, and is carried thence downwards by the reflux stream, in some cases towards the apex, in some along the sternum, generally diminishing in intensity in its passage, and possibly even undergoing some change of quality. Occasionally it is most distinct midway between the left nipple and the edge of the sternum, or even over the lower part of the sternum or at the apex. It is in general rapidly lost along the ascending arch. It occurs alternately with the carotid pulsations and cardiac impulses.

ii. *Pulmonic valve disease*.—A *systolic murmur* produced at the pulmonic orifice is heard loudest over the left edge of the sternum, at about the level of the third costal cartilage. It is heard also over the trunk of the pulmonary artery, namely, at or about the left edge of the sternum, as high as the upper border of the second cartilage. But it is inaudible, or nearly so, to the right of the sternum and along the ascending aortic arch, and fades away as it is traced downwards over the right ventricle. Organic murmurs at this orifice are rare, excepting as the result of congenital disease. *Regurgitant murmurs* from defect of the pulmonic valve are extremely uncommon. They are best heard over the diseased valve, and thence downwards towards the right apex.

iii. *Mitral valve disease*.—Of all murmurs the *systolic mitral*, or that due to regurgitation through the mitral orifice, is the most common. It attends the systole of the heart, and, therefore, like the direct aortic, is synchronous with the carotid pulse. It is usually heard most distinctly, not immediately over the valve, but over that part of the left ventricle which is most superficially placed, namely, the apex. If feeble it may be audible in this position only, but if loud it is often heard over the whole of the præcordial region. In the latter case it generally diminishes in force from the apex to the base; but occasionally increases again over the aortic orifice or ascending arch. A systolic regurgitant murmur is carried back with the reflux blood into the left auricle; and partly on this account, partly because of the situation of the left ventricle to the left and back of the heart, it is generally distinctly audible about the angle of the left scapula, and along the horizontal line passing from this point to the apex of the heart—a fact of great importance in the recognition of this murmur. *Direct* or *obstructive mitral* murmurs occur during the diastolic period, and until of late years were generally overlooked or misinterpreted. They are often absent because, although obstructive disease is not uncommon, the force with which the blood passes from the auricle into the ventricle is generally insufficient to generate a murmur. It is well known, however, to physiologists that during the earlier period

of the ventricular diastole the blood is flowing almost passively through the auricle into the ventricle, and that it is only at the last, just before the ventricle itself contracts, that the auricle contracts and propels its blood with vigour. It is at this moment, therefore, that a murmur is most likely to be developed. It need scarcely be added that, when the auricle has become, as it soon does, dilated and hypertrophied, and the time occupied in discharging its contents more or less protracted, the murmur is likely to be rendered both more intense and of longer duration.

A direct mitral murmur may occur either at the beginning, in the middle, or at the end of the diastolic period, or may occupy the whole of that period. In the first case, the murmur (like an ordinary diastolic

FIG. 53.—GRAPHIC REPRESENTATION OF MITRAL MURMURS.

1, 2. First and second sounds respectively. *a*. Systolic murmur.  
*b, c, d, e*. Varieties of obstructive murmur.

murmur) runs off from the second sound of the heart, and ceases before the occurrence of the first. In the second case, the murmur is heard at a definite, but short, interval after the second sound, a definite and usually longer interval intervening between it and the first. We believe that this is sometimes merely an ordinary diastolic murmur, beginning from the later element of a reduplicated second sound due to the lagging action of the left ventricle. But we are satisfied that in many it is an independent mid-diastolic murmur. The third variety of murmur begins somewhere in the diastolic period, and runs with gathering force into the second sound. This is the most common and best recognised variety of obstructive mitral murmur. It has been termed by Dr. Gairdner auricular systolic, from its production during the contraction of the auricle and while the contents of that cavity are being driven forcibly into the ven-

tricle, but is generally known as the presystolic murmur because of its relation to the ventricular systole. Occasionally the three above described murmurs run together, and the whole of the diastolic period becomes occupied by a continuous roar starting from the second sound, and terminating with the first sound with both of which it blends. Diastolic mitral murmurs are always rough in quality, having a close resemblance to the trilled *r*; and the presystolic, with its culmination in the first sound, reminds one of the roar of a wave breaking in the hollow of a rock. They are heard, as a rule, over a comparatively small area at the apex of the heart, or a little to its inner side, or above it, and rarely (if ever) at the base or in the axilla. Moreover, they are very irregular and unequal in their production, and are liable to disappear wholly or in part when the circulation is tranquil, and to become again distinct when the heart's action is excited.

iv. *Tricuspid valve disease*.—Disease of the tricuspid valve is comparatively rare; it is also rare to have a murmur produced at this orifice. A *direct* murmur, or one attending the ventricular diastole, is of exceedingly unfrequent occurrence. Its rhythm corresponds to that of the presystolic mitral, but it is audible over the right ventricle, and according to Dr. Hayden chiefly over the left fifth costal cartilage and the fourth intercostal space close to the sternum. A *regurgitant* or *systolic* murmur is much more common; but this is more frequently due to over-distension or dilatation of the ventricle or comparative shortness of the muscoli papillares, and consequent inadequacy of the valves, than to their structural disease. It is sometimes observed in the displaced hearts of persons suffering from angular curvature of the dorsal vertebræ, in whom also the right ventricle is occasionally much hypertrophied. The murmur is generally somewhat low-toned, audible most distinctly about the ensiform cartilage, diminishing thence towards both the left apex and the base, and absent at the back of the chest.

v. *Multiple valve disease*.—Of course it is possible that only one valvular defect may be present at any one time; but it is very common for two or more defects to be associated, and consequently for several murmurs to occur simultaneously. Thus there may be a double aortic murmur, causing a to-and-fro sound, and simulating pericardial friction, for which it is often mistaken; or there may be a double mitral murmur, in which case the presystolic sound runs into the systolic bruit; or there may be combinations of aortic and mitral murmurs. Murmurs developed at the right side of the heart also may be associated with murmurs arising on the left side; and indeed it is by no means uncommon for a mitral murmur to be followed after a time by a regurgitant tricuspid murmur, due to the gradually developed hypertrophy and dilatation of the right ventricle which supervene on mitral disease, and the resulting tricuspid incompetence. In differentiating the murmurs due to different valves, when more than one valve is affected, it is necessary not only to have regard to other signs and symptoms which the patient may present, but to determine accurately the points at which the murmurs are heard

with chief intensity, and where they fade away or seem to alter in character.

*f. Other physical signs* may assist in the diagnosis of valvular lesions. As we have already shown, when speaking of cardiac hypertrophy and dilatation, the shape and dimensions of the præcordial dulness, and the position and character of the apex-beat, are important aids to us in determining the size and form of the heart, and whether, therefore, we have hypertrophy and dilatation of the left ventricle, as are met with in aortic valve disease, or whether we have hypertrophy and dilatation of the right ventricle, as occur in mitral, pulmonic, and pulmonary diseases. *Tremor* or *fremitus* may accompany all forms of valve disease, but mainly attends such as cause rough or deep-toned murmurs. Valvular tremors generally occupy a circumscribed area: they are felt over the ascending arch and pulmonary artery in obstructive disease of the aortic and pulmonic valves respectively, over the base of the heart and the large vessels in aortic regurgitation, and at the apex in mitral affections. The most common and most pronounced thrill is that felt over the apex of the heart in association with presystolic murmurs. Lastly, it may be pointed out that in mitral valve disease the second sound of the heart becomes accentuated to the left of the sternum, where it is often found markedly louder than in the neighbourhood of the right second costal cartilage. This phenomenon appears to be connected with the enlargement which in this case takes place in the right ventricle.

*g. The effects of valve disease on the general organism.*—An account of valvular lesions and of their diagnosis would be singularly inadequate if it were limited to the phenomena presented by the heart itself. A valvular defect, whether causing obstruction or inadequacy, may be so slight as, although causing a murmur readily detectable by the stethoscope, to have no appreciable influence either on the heart itself or on the circulation. More commonly the defect is sufficiently serious, first, to cause enlargement of one or more of the chambers of the heart, and next, to embarrass the circulation of blood through the pulmonary or systemic vessels, or both. As a general rule, the parts in front of an actual or virtual obstruction tend to become anæmic, while those behind it tend to become congested.

In *obstructive aortic disease* the pulse is usually regular, and according to the degree of obstruction tends to be small. The associated hypertrophy of the heart, however, may for a time at any rate neutralise this latter tendency, and especially cause prolonged elevation of the systolic element of the pulse. This affection often goes on for a long time without causing much inconvenience. But sooner or later pain and palpitation and breathlessness supervene; the pulse becomes feeble and irregular, the arteries unfilled, and syncopic and epileptiform attacks liable to come on; or pulmonary and systemic venous engorgement occurs, with various consequences, which will be considered when we come to speak of mitral disease.

In *regurgitant aortic disease* the pulse, as in the last case, is usually regular, but it presents a peculiar jerky quality, which is due to a combination of sudden violence and fulness of the systolic wave and its sudden collapse. It is the pulse of unfilled and flaccid arteries, and, though general in aortic regurgitation, occurs under other circumstances. The sudden rise and the sudden fall are both comprised within the period of the cardiac systole, so that the latter element is not directly referrible to regurgitation. The dicrotic rise, however, as a rule, is almost or wholly suppressed; a phenomenon which modifies the pulse trace, but is probably imperceptible to the touch. This variety of pulse, which has been likened to the passage of shot under the finger, is variously known as Corrigan's, the 'water hammer,' or a collapsing pulse. It is always specially observable in the vessels of the neck and in the subclavians, whose pulsation is sometimes so visible and so violent as to suggest the presence of aneurysmal dilatation. It generally becomes more obvious at the wrist when the forearm is held in the perpendicular position. It may be detected even in the *arteria centralis retinae*; and in the capillary vessels, when a superficial area has been rendered partially anæmic by pressure. The last phenomenon may be evoked by drawing the finger-nail across the forehead, or better, by firmly pressing a glass slide on some prominent rosy part, such as the lip, and observing through the glass the rhythmical variations of colour which ensue. It may often, also, be observed in the finger-nail. In regurgitant aortic disease the patient suffers more from deficiency of blood in the arterial system than in any other form of cardiac lesion. He generally becomes notably pallid, much more liable than in simple obstructive disease to syncopic and epileptiform attacks, and often dies suddenly. He is also apt to suffer from palpitation, breathlessness, and angina-like attacks. In this case, as in the last, the effects of venous obstruction may ensue sooner or later.

Both forms of *mitral disease* are characterised by a tendency to feebleness and irregularity of pulse. Indeed, these qualities of pulse are usually developed at a comparatively early stage, and become extreme with the progress of the disease. They are due partly to the incomplete filling of the left ventricle, partly to an irritable state of its walls resulting from its comparative emptiness. In mitral as in aortic valve disease the patient may suffer from tendency to syncope and other consequences of imperfectly filled arteries. He may suffer also from angina. But the special characteristic of mitral disease is its tendency to cause, at a comparatively early period, congestion first of the pulmonary circulation, and then of the systemic veins, and phenomena dependent on such congestions. In connection with the pulmonary stasis arise congestion and œdema of the lungs, effusion of blood into the pulmonary tissue (pulmonary apoplexy), thrombosis of the pulmonary arteries, tendency to inflammation, and all the symptoms (lividity, dyspnœa, cough, hæmoptysis) which flow from such affections. In dependence on the sluggish movement and accumulation of blood in the systemic veins are developed: general dilatation of veins and capillaries, with congestion specially

observable in the hands and feet and face, and tendency to hemorrhage, mainly perhaps petechial extravasation into the connective tissue of the lower extremities; anasarca, chiefly of dependent parts; dropsy of serous cavities; and thrombosis. Further, the liver becomes congested and indurated, and assumes the well-known nutmeg character, and jaundice and other consequences of hepatic disorder ensue; the kidneys get similarly affected, and the urine grows scanty and albuminous; not unfrequently the gastro-intestinal tract undergoes functional disturbance, or becomes the seat of hemorrhagic effusion or organic lesions; also the central nervous system suffers, and headache, vertigo, and delirium ensue, or drowsiness and coma, or even hemorrhage from laceration of cerebral vessels.

There are two or three other occasional consequences of venous obstruction which claim attention. These are pulsation of the larger veins; pulsation of the liver; and bulbous enlargement of the terminal phalanges of the fingers and toes. (i.) Venous pulsation is observed mainly in the veins at the root of the neck, but it may be visible even in the veins of the extremities. It is due, as a rule, to the fact that, owing to their dilatation, their valves allow of regurgitation, and that at the same time during the contraction of the right ventricle regurgitation takes place through the tricuspid orifice. It is usually, therefore, a proof of incompetence of the tricuspid valve, and that the right ventricle has undergone hypertrophy and dilatation. The pulsation in marked cases may be not only seen, but felt; and the sphygmographic tracing displays a double rise, of which the second is far more ample than the first, a circumstance which is due to the fact that the latter is caused by the auricular contraction, the former by that of the ventricle. It must not be forgotten, however, that pulsation of the veins at the root of the neck may be caused simply by auricular contraction when the veins are full, and that it may be simulated by the rhythmical distension of the veins which takes place during expiration, and by pulsation transmitted from neighbouring arteries. (ii.) It was first shown by Friedreich, and has since been confirmed by other observers,<sup>1</sup> that, under similar circumstances to the above, hepatic pulsation not unfrequently occurs. It seems to be due to regurgitation into the vena cava ascendens, and thence into the hepatic veins. The pulsation (which must be distinguished from ordinary epigastric pulsation, due to the direct influence of the action of the heart, or of the abdominal aorta) is visible over the whole extent of that portion of the abdominal surface with which the distended liver is in immediate relation, and may in many cases (especially if the enlargement of the liver be considerable) be felt, on grasping the hepatic zone with the two hands, to be distinctly expansile. The sphygmographic tracing which may be obtained from the pulsating organ presents the same characters as that yielded by the venous pulse, and indicates a like origin. (iii.) In cases of long-continued venous obstruction (and especially, therefore, in heart-

<sup>1</sup> Dr. Frederick Taylor, *Guy's Hospital Reports*, 1875.

disease of congenital origin) the last phalanges of the toes and fingers become livid and swollen or bulbous—a condition which is also observed in phthisis and several other affections.

6. *Inorganic or Hæmic Murmurs of Heart and Murmurs in Blood-vessels.*

Murmurs which it is sometimes impossible to distinguish from the murmurs of valve disease are often audible over the præcordial region, and in the neighbourhood of the large vessels at the base of the heart. Some of these are referrible to the heart itself, some to the arteries, some to the veins, some to the pericardium, and some probably to the lungs.

a. Not unfrequently, even in healthy persons, when the heart is beating violently under the influence of vigorous bodily exercise or strong mental excitement, a loud blowing, sometimes musical, systolic murmur is developed at the aortic orifice and along the aortic arch. This is due simply to the unwonted force with which the blood is propelled from the ventricle through the arterial orifice.

b. Cardiac murmurs, not due to cardiac disease, are of common occurrence in chlorotic girls and other persons who are suffering from anæmia. Similar murmurs are also sometimes present in persons whose blood appears to be in a healthy state. These are systolic, and usually heard at the base of the heart, either in the aortic or in the pulmonic area, and are generally supposed to be referrible to one or other of the arterial orifices. They are sometimes simple blowing murmurs undistinguishable from murmurs of organic origin. But those heard in the pulmonic area are very often of a peculiar rough, crepitating, or ‘scratchy’ character (Sibson), sharper or higher pitched than mitral obstructive murmurs, and possibly quite as loud. These latter murmurs are peculiar in the fact that they sometimes run off from the first sound, sometimes run up to the second sound, and not unfrequently occupy the whole of the systolic period; presenting in fact the same relation to this period that obstructive mitral murmurs bear to the period of diastole. They are also increased by pressure and modified by respiration. From their peculiar characters it is often difficult not to believe that they are of organic origin; they are specially apt to be mistaken for the sound of pericardial friction, and indeed cannot always be distinguished from it. It is certain, however, that in most cases these murmurs are unassociated with any cardiac lesion. The murmurs heard in the course of the aorta are doubtless aortic. Those heard in the situation of the pulmonary artery, which are the most common, are held by Dr. Balfour (adopting Naunyn’s views with respect to the conveyance of mitral regurgitant murmurs into the left auricular appendage) to be due to mitral regurgitation. If this were true, however, we ought to be able to hear ordinary regurgitant mitral murmurs best or alone in the same situation. The explanation of these so-called ‘hæmic’ murmurs developed at the arterial orifices is not very clear. By some they are supposed to be due to mere poorness of blood, by some to

incomplete filling of vessels, by some to suddenness and rapidity of escape of blood from the heart. We are inclined to suspect that the common rough murmur audible over the pulmonary artery may be the consequence either of coarse, rustling vibrations in the walls of this vessel while it is undergoing dilatation, or due to the influence of this dilatation over the adjoining auricular appendages. When endocardial murmurs are developed towards the apex, they are due to regurgitation through the tricuspid or mitral orifice, which must therefore be incompetent. We have shown that such incompetence may exist physiologically on the right side; and there is no doubt that it may be developed upon either side in consequence of weakness and dilatation of the ventricles. Hence it becomes possible that systolic mitral or tricuspid murmurs may be due indirectly to anæmia, and may disappear, like the truly functional basal murmurs, with improved health.

c. A systolic murmur is sometimes audible at the apex of the heart, which has been attributed, and we think correctly, to the sudden expul-

FIG. 54.—GRAPHIC REPRESENTATION OF SPECIAL MURMURS.

1, 2. First and second sounds of heart respectively. *a*. Functional basic cardiac murmur. *b*. Apex murmur, probably inorganic. *c*. Murmur of communication between aorta and cava, or in arteries beyond seat of partial obstruction.

sion of air from the portion of lung lying over the apex during its systolic impulse—to a similar mechanism, indeed, to that which causes *bruit de pot fêlé* at the upper part of the healthy chest in young children. This murmur is soft or high-pitched, is heard over a small area only, never in the back, and varies with the respiratory movements, being generally loudest during respiration, especially inspiration, and often inaudible when the chest is fully expanded, contracted, or at rest. Its diagnosis would be aided by the fact of the absence of all other signs of cardiac disease.

This murmur seems to be produced in the same way as the form of wavy or jerky respiration often heard over the lungs, in the neighbourhood of the heart, especially when the heart is acting with undue violence or the lung is the seat of partial consolidation. Indeed the impulses of the wavy respiration occasionally become distinct murmurs along the margins of the præcordial area.

It may be conveniently mentioned here that now and then a soft systolic murmur, presenting all the characters above described, excepting

that it begins after the first sound and runs into the second, is occasionally observed.

Basic cardiac murmurs are occasionally manufactured or modified, especially in children, by the pressure of the stethoscope.

*d. Arterial murmurs.*—Murmurs may arise in arteries from simple undue rapidity of flow of blood along them, as sometimes happens during violent palpitation of the heart from over-exercise or strong emotion. Under such circumstances, the subject of palpitation often hears with painful distinctness the murmurs developed in his own carotids and their branches. Such murmurs are no doubt more readily producible in anæmic than in healthy persons. Arterial murmurs also occur when the walls of arteries are rough and irregular from atheroma or other degenerative changes, and in cases in which the channel is diminished, whether from adherent clot within, from thickening of the walls, or from pressure from without, and even when it is dilated. It is frequently from one of these latter causes that murmurs attend the presence of aneurysms. Tumours pressing on arteries, or involving them, commonly cause murmurs; and hence abdominal tumours, and growths in the mediastinum or root of the lung, are occasional causes of murmurs within the abdominal and thoracic cavities respectively. Murmurs referrible to the innominate, or first part of the left subclavian, are occasionally due to the pressure of the lungs during the respiratory movements, and are often developed in the third part of the subclavian, as they may also be in the abdominal aorta and superficial arteries, by the pressure of the stethoscope. Lastly, murmurs are often carried by the blood-stream to a considerable distance from their point of development. The murmurs commonly heard over aneurysms of the aortic arch are to a large extent merely the murmurs of accompanying aortic valve disease. And, as we have already shown, aortic valve murmurs, and more especially systolic murmurs, are often distinctly audible in the whole length of the aorta. Occasionally, especially in arteries at a little distance from the heart, as for example in the abdominal aorta, a systolic murmur of local origin is prolonged, with some modification of character, into the diastolic period, and thus, though wholly independent of regurgitation, simulates a double aortic valvular murmur. A murmur of this kind, accompanied by a marked thrill, and presenting somewhat the character of a venous murmur, may often be heard in the neck, especially on the right side, in cases of goitre. The murmur and thrill are most pronounced above the level of the tumour, and are evidently due to the fluid vein, determined by the flattening of the vessel behind the tumour, in the uncompressed portion of vessel above it.

*e. Venous murmurs (bruit du diable),* consisting of a continuous humming or buzzing, whistling or hissing, are not uncommonly audible in the larger veins when they are partially obstructed, and especially in anæmic patients. They may generally be best heard in the neck, particularly on the right side. They are largely determined by the pressure of the stethoscope, are modified by the respiratory acts, and are most readily obtained when the patient is erect. A similar musical sound may

sometimes be heard in the chest at the base of the heart, or over the large vessels (mainly on the left side) at the end of inspiration or expiration. It is clearly a venous hum, and referrible either to the innominate or to the pulmonary veins. Venous murmurs may be caused by the pressure of tumours on veins, and thus may be extensively audible in the neck and chest in cases of thyroïdal or mediastinal tumours. They are not uncommon about the *scrobiculus cordis* in cases of chronic hepatic disease and ascites.

*f. Arterio-venous murmurs.*—When from any cause an artery communicates with a vein, as for example when an aneurysm of the aortic arch opens into the superior cava or one of the innomates; or when an opening forms between the aorta and pulmonary artery or an auricle, a murmur is apt to be developed which is more or less musical, and which beginning with the cardiac systole is continued through it into the diastolic period, in the course of which it dies away. Such a murmur, which is very characteristic, may, when occurring in the vicinity of the heart, be carelessly mistaken for a double aortic murmur.

## 7. Motor and Sensory Derangements

*α. Motor derangements* reveal themselves by undue feebleness or force, frequency or infrequency of action, by intermission or irregularity, or by sudden arrest of action from spasm or paralysis. Several of these are only exaggerations of conditions which are compatible with health. *Feebleness* of the heart's action attends most wasting diseases and the later period of many febrile and other acute affections. It is common also in mitral disease, and in some other morbid conditions of the heart. It is characterised by weakness of apex-beat; diminished intensity of the cardiac sounds, especially the first, which may be absolutely abolished; feebleness of pulse, which is undulatory, thready, or markedly dicrotous, and may be imperceptible at the wrist, even while maintaining a distinctly dicrotous character in the larger arteries; and lastly, a great tendency to variation in the rate of the pulsations under the slightest disturbing influences. *Increased force* of cardiac action tends to take place whenever any impediment to the flow of blood occurs either at the aortic orifice or in the course of the arteries, in the capillary vessels or in the venous system. It is common, therefore, in aortic valve disease, in the presence of rigid arteries, and in Bright's disease. It may also occur in inflammatory disorders, during muscular exertion, and under the influence of nervous excitement. The indications of this condition are, violence and extension of the cardiac impulse, which is often prolonged and heaving, and may be felt in the back and even shake the entire body; loudness of the cardiac sounds; and hardness of pulse. *Increased frequency* of pulsation occurs under many different conditions; such as nervous excitement, debility, febrile disease, and so on. The individual pulsations may be weak or strong, and the characters presented by the cardiac movements, its sounds, and the arterial pulse will correspond. *Diminished frequency* of pulsation

is common in convalescence from acute disorders. It is also met with in some cerebral affections and in some cases of cardiac disease. The pulsations of the heart may run up to 200 or even 300 in the minute, and may fall to 20 or even 12. The term *palpitation* is commonly used of those conditions in which, under the influence of nervous excitement, the pulsations of the heart, arteries, or both, are painfully evident to the patient himself; the beats are frequent, sudden, and violent, and the pulse often attended with marked diastolic murmurs. *Irregularity* of the cardiac rhythm is occasionally observed in gout and indigestion, but is most frequently

FIG. 55.—PULSE-TRACINGS IN DISEASE.

associated with various forms of heart disease, and especially with affections of the mitral valve. It is manifested by inequality of the successive pulsations, as regards both force and fulness, and the length of the interval which elapses between them. *Intermission* of action is a form of irregularity which is mostly functional; it is common in dyspepsia, and is occasionally a constitutional peculiarity of the patient. In intermission the general rhythm of the heart's action is not impaired, but at regular or irregular intervals a beat is dropped, as it were. At the wrist it is wholly absent; on listening to the heart, however, the intermission is

represented by an abortive throb, followed by a pulsation of greater intensity than those which follow next. Occasionally such abortive strokes may occur alternately with effective ones, and the pulsations at the wrist be half as numerous as the cardiac beats. *Sudden arrest* of the heart's action, and consequent death, may be caused by shock, or syncope, and is not uncommon in certain forms of heart disease.

FIG. 56.—PULSE-TRACINGS IN DISEASE.

Asynchronism in the action of the ventricles, indicated by reduplication of the sounds of the heart, is not unfrequently observed. Occasionally it occurs in health, but much more commonly it is an accompaniment of disease. Reduplication of the first sound is chiefly met with in connection with hypertrophy of the heart and high arterial tension, especially there-

fore in chronic heart disease; and reduplication of the second sound is observed mainly in affections of the mitral valve.

*b. Abnormal sensations* are frequently associated with cardiac affections. In palpitation the pulsations of the heart and often of the larger arteries are distinctly felt and complained of by the patient. When intermission takes place the sufferer generally experiences a kind of throb, or tumble in the region of the heart, or a choking sensation which may be attended with momentary faintness. A feeling of oppression at the chest, or fulness, or aching, is not uncommon. And sometimes the pain may be intense, prolonged, and indeed unbearable, extending over the whole cardiac region, or limited to some definite part of it, and often radiating thence to various parts of the trunk and to the extremities, especially down the arms.

### 8. *Prognosis of Cardiac Derangements*

Our remarks under this heading will have reference almost exclusively to valvular lesions, and the conditions which are associated with them.

*a. Hypertrophy* is in most cases compensatory, and therefore, at any rate for a time, rather a benefit than an injury to the patient; dangers, however, follow in its train, the more important of which are dilatation of cavities, incompetence of valves, and degenerative changes in the muscular tissue of the heart itself and in the arterial system—all of them indications and sources of failing strength.

*b. Whenever a diseased heart becomes also enfeebled*, the symptoms from which the patient suffers are greatly aggravated. Weakness of the heart, indeed, whenever it occurs apart from and out of proportion to weakness of the general system, is always of grave import.

*c. In attempting to estimate the relative prospects of life of patients suffering from the various forms of valvular lesions*, many different matters have to be taken into consideration. Thus, if the affection be due to rheumatic inflammation, we know that the patient has special liability to a recurrence of his rheumatism, and consequently to aggravation of his cardiac malady; if the disease be the consequence of senile changes, we know that the valve affection must, in the nature of things, be progressive; and both in these and in other cases there is often something in the condition of the valves, only to be guessed at during life, which renders the danger of embolism always imminent. Again, the constant bodily or mental labour to which many sufferers are condemned necessarily influences symptoms unfavourably and hastens death; further, any conditions of failing health which tend to enfeeble the muscular walls of the heart tend, on this very account, to affect injuriously in a disproportionate degree the due action of the organ, and to expedite the fatal issue; and last, inflammatory and other affections of the lungs, which embarrass the pulmonary circulation, form especially serious and dangerous aggravations of all forms of heart-disease.

But, putting aside all these sources of danger, which are more or less accidental, and common to most varieties of heart-disease, the question

remains, 'what, *cæteris paribus*, are the relative prospects of life of those suffering from the different valvular lesions?' and (it may be added) 'what are the special dangers to which they are respectively liable?' Obstructive disease at a valvular orifice is, other things being equal, a much less serious matter than regurgitant disease, inasmuch as the hypertrophy of the muscular walls of the cavity behind becomes for the most part accurately adjusted to the increased work which is thrown upon them. The adjustment is often so accurate in the case of aortic valve obstruction, that persons thus affected live for years unconscious of the presence of disease. Indeed, this is certainly the least serious of all valvular lesions. Obstructive mitral valve disease, again, unless it be extreme, is pretty successfully counteracted by hypertrophy of the left auricle. Compensative hypertrophy of the auricle, however, can scarcely be so efficacious as that of the ventricle, since the absence of valves at the entrance of the veins allows the increased blood-pressure to be easily propagated backwards through the pulmonary vessels. It is certain, indeed, that in a large proportion of these cases symptoms of cardiac disease manifest themselves before long; but, on the other hand, it is also certain that many persons who labour under congenital constriction of the mitral orifice live for many years, and for a large portion of their lives suffer little. No degree of hypertrophy can neutralise the effects of regurgitation. Indeed, it is questionable whether the hypertrophy which always follows on regurgitation is in any degree compensative of that regurgitation; whether, indeed, it is not to be regarded as the result of an effort to neutralise the virtual weakness which the dilatation, always attending regurgitation, causes. Aortic regurgitant disease is probably the most serious and rapidly fatal of all forms of valvular lesion. Regurgitant disease of the mitral is certainly less serious than the last, and patients often labour under it for many years; nevertheless, it is probably more dangerous than obstructive disease of the same orifice. The order of danger in which Dr. Peacock places the four lesions which have just been considered, and we concur with him in this matter, is as follows: first, aortic regurgitant; second, mitral regurgitant; third, mitral obstructive; and fourth, aortic obstructive. It need scarcely be remarked, however, that this order is necessarily often departed from; that regurgitation (although productive of a murmur) may be so slight as to be of comparatively little moment; that obstruction may be so extreme as to lead to the rapid destruction of life. Diseases of the right side are so rare, and when present so often associated with lesions of the left side, that it is impossible, excepting theoretically, to estimate their relative degrees of danger.

We have previously discussed the various consequences of heart-disease; and from what was then said the causes of death in patients suffering from valvular lesions may for the most part be determined. Sudden death, which was formerly so largely attributed to heart-disease, is not a common sequela of valvular lesion. It is most common in regurgitant aortic disease, and in that case is due to syncope, or perhaps, as some maintain, to cardiac anæmia from non-filling of the coronary arteries.

d. In relation to the subject of prognosis we may briefly allude to the occasional apparent cure of valvular lesions, and to the not unfrequent persistence of cardiac disease for years with little or no obvious impairment of health. The longer one's experience extends, the more one's belief becomes confirmed that murmurs arising during rheumatism, and presumably therefore of organic origin, not unfrequently disappear permanently. It may be assumed that a rigid valve never again becomes normally pliable, that a contracted or shrunken valve never re-attains its original dimensions and form, and that inflammatory vegetations always leave some trace of their former presence. Still slight thickenings and scanty vegetations, sufficient at the time of their formation to disarrange the action of the valves, may doubtless so far become effaced with the cessation of the inflammation that caused them that the valves become restored to a condition of practical healthiness. Experience also shows that the presence of obvious and apparently serious heart disease is not unfrequently compatible with long life and good health. And this is true, not only of adherent pericardium and of mitral regurgitation, but of all other valvular lesions and even of aortic regurgitation and multiple valvular affections. In explanation, it must be borne in mind that the loudness of murmurs has no definite relation to their seriousness, and that within certain limits compensatory changes are protective. And at any rate, in judging of the prospect of life in persons who have had cardiac lesion for some length of time, we must consider, not merely the kind of disease present, but the effect which the disease has had upon the structure and functions of the heart, and the absence or presence of secondary affection of other organs, and of impairment of the general health.

### 9. *Treatment of Cardiac Derangements*

a. The treatment of simple cardiac hypertrophy is a matter of simplicity. We can only remove hypertrophy by removing or obviating the lesion which has provoked it, by maintaining the circulation in an equable and quiet condition, by the avoidance of mental and bodily excitement or over-exertion, and by careful attention to the healthy maintenance of the functions of the body generally. It is, however, of the highest importance to delay or prevent the supervention of that enfeebled condition of heart in which hypertrophy so commonly and disastrously ends; and this must be effected by promoting the general health of the patient, for which purpose iron and other tonics, change of air, and nourishing diet are often necessary.

b. The treatment of cardiac debility differs little, if at all, from that needed in the later stages of valvular, and more especially mitral valvular, disease, a subject presently to be considered.

c. In treating valvular diseases we must never forget that we are dealing with affections which, in the nature of things, are for the most part incurable; that valvular defects tend, on the whole, to increase; that their ill effects tend gradually to become augmented by the changes which take place secondarily to them in the walls and dimensions of the cardiac

chambers, and are always liable to serious aggravation by the presence of any condition, be it normal or morbid, which embarrasses the circulation. Our primary object must, therefore, be to prevent, or at all events to delay, the supervention of those numerous morbid processes and symptoms which have already been adverted to as the consequences of heart disease. We cannot repair the injured valve. We cannot, and should not if we could, prevent the compensatory hypertrophy which ensues; we may, however, by forbidding excessive muscular exertion, or taking precautions against mental excitement, or other provocatives of increased cardiac action, prevent in many cases that hypertrophy from becoming excessive, and therefore injurious. We cannot prevent a certain amount of dilatation from taking place in association with hypertrophy; but by the same measures by which we counteract the one we tend also to counteract the other; and further, since dilatation is to a large extent dependent on impairment of muscular strength, we may, by maintaining the general strength, maintain also to some extent that of the heart itself. Lastly we may often succeed by careful attention in preventing the recurrence of inflammatory attacks, in arresting pulmonary and other congestions which react deleteriously on the heart, and in maintaining the quality and quantity of the blood in a fairly normal condition.

Hence a patient whose heart is obviously diseased, and especially one who already suffers from cardiac symptoms, should abstain from all forms of violent and sustained exertion, and should never push even what seems to be moderate exercise to the extent of causing shortness of breath, or palpitation, or uneasy feelings of any kind, or even fatigue. His pursuits and surroundings should be such as do not entail mental excitement. He should be protected by proper clothing and other precautionary measures against cold. His bodily health should be maintained by the use of wholesome, nutritious, but not too abundant food, by the cautious employment of stimulants, and by carefully regulating the action of his emunctories.

But, notwithstanding the greatest care, a time tends to come sooner or later, and comes soon to those who are compelled to work hard for their livelihood, when the consequences of the cardiac lesion become painfully apparent. The patient begins to suffer from palpitation, irregularity of pulse, shortness of breath, dropsy, jaundice, albuminuria, pulmonary apoplexy, angina. But even in these cases it is remarkable how often, under the influence of perfect rest and the other items of treatment which have been enumerated, all unfavourable symptoms subside. Indeed, in the treatment of the symptoms and consequences of valvular disease there is no doubt that absolute rest is of far more value as a remedial agent than anything else that can be named. But in aid of rest other agents may often be beneficially employed. Frequency of pulsation, and especially irregularity, are almost invariably connected with feebleness and irritability of the heart's action. To remedy this condition it seems desirable first to give strength to the heart's contractions, and next to diminish their frequency. For the former of these purposes iron and the

vegetable tonics, and possibly *nux vomica*, are valuable; for the latter no drugs, at any rate in mitral valve disease, are so efficacious as *digitalis* and *strophanthus*. A combination of either of these with iron is often of very great value. *Belladonna* is by many preferred to *digitalis* in the treatment of lesions of the aortic valve. To relieve the overloaded venous system, to which so many of the resultant phenomena of valvular disease are due, we may employ diaphoretics, diuretics, and purgatives, and besides these, in some cases, the removal of blood by leeches or cupping, or by venesection. Further, to relieve shortness of breath or engorgement of the lungs, or præcordial uneasiness, ether, ammonia, lobelia, stramonium, squills, ipecacuanha, or other expectorants, opium and counter-irritants, may all of them, under slight modification of circumstances, be of use.

## II. PERICARDITIS, MYOCARDITIS, AND ENDOCARDITIS

### A. *Pericarditis*

*Causation*.—Inflammation of the pericardium is evoked in various ways: by extension from the muscular walls of the heart when these contain abscesses; by extension from the pleura, peritoneum, cellular tissue of the neck, posterior or anterior mediastinum, or any other neighbouring part which is the seat of inflammation; by local injuries, such as penetrating wounds of the pericardium, or the opening into it of sinuses from hepatic or other abscesses, and by the rupture of aneurysms, hydatid cysts, and the like. The most frequent and important cause of pericarditis, however, is exposure to cold and wet, especially if that exposure results in the development of rheumatic fever. Pericardial inflammation occurs not unfrequently in association with, if not in dependence upon, chronic albuminuria, scarlatina, chorea, pyæmia, and occasionally in connection with tubercular, syphilitic, and carcinomatous or other malignant growths. It often occurs concurrently with other forms of intra-thoracic inflammation.

*Morbid anatomy*.—Inflammation of the pericardium, like that of all other serous membranes, is characterised in the first instance by dilatation of the blood-vessels and consequent hyperæmia, effusion of their fluid contents into the substance of the serous membrane, and into the subserous tissue, and tendency to proliferation of the endothelium. At first, little more than simple congestion and oedematous thickening of the membrane is present. But soon inflammatory exudation takes place, consisting partly of fibrine, which as it is secreted coagulates upon the surface, and remains adherent to it or blended with it; partly of serum, which containing dissolved albumen and fibrinogen accumulates in the pericardial cavity, and separates one surface of the membrane from the other; and partly of inflammatory corpuscles, derived either from the proliferating

endothelium or from errant leucocytes of which the majority remain entangled in the coagulating fibrine.

The relative quantities of solid and fluid exudation, their characters, and the changes which they undergo, present great varieties. In some cases of pericarditis, which is thence often termed 'dry,' the whole surface becomes covered with a greater or less abundance of false membrane, but there is little or no accompanying serous effusion. In most cases, however, a few ounces of fluid are poured out in the course of the affection. And occasionally the accumulation amounts to two or three pints, or more.

The solid exudation or false membrane forms in the early stage of its production a thin, slightly coherent lamina, which is scarcely distinguishable except from the fact that it robs the serous surface of its normal smooth glistening aspect. But it soon increases in quantity by the addition of fresh inflammatory matter to its free surface, and may thus by degrees attain the thickness of paper, cardboard, or of  $\frac{1}{4}$  or even  $\frac{1}{2}$  inch. As its thickness increases, so also, as a rule, do the density and closeness of adhesion of its deep surface, and the irregularity of its free aspect. At first the latter is merely faintly granular, but it soon gets villous or tuberculated, or pitted with irregular and deepish holes. It is difficult to give in a few words a notion of the different appearances which may be presented; in some cases the surface is honeycombed; in others it is ribbed like the sand which the waves have just left; in others it has the aspect which may be produced by separating two hard smooth surfaces which have been stuck together with a layer of butter; in others the exudation has been rolled by the to-and-fro movements of the heart into fusiform pellets, which remain irregularly attached to one or both surfaces of the pericardium; occasionally it presents a uniform villous character. Further irregular bands, festoons, or laminæ of the same material not unfrequently extend between the visceral and parietal layers.

The pericardial fluid is sometimes limpid and colourless, almost like water, sometimes opaline, and occasionally distinctly tinged with blood.

In many cases, no doubt, inflammation commences at some one spot or circumscribed area of the serous membrane; and, indeed, in mild cases it not very unfrequently remains thus limited, or at all events does not become general. More frequently the whole of the pericardium is involved.

In the great majority of cases of pericardial inflammation, resolution takes place after a longer or shorter period. The fluid which has been effused undergoes absorption; the false membrane becomes organised, contracts, hardens, and ultimately is converted into an imperfect form of connective tissue. In some instances circumscribed inflammatory patches result in the formation of those opaque, white, cicatrix-like thickenings which are so commonly met with on the surface of the right ventricle, and are known as 'milk-patches.' In some such cases the opposed pericardial surfaces become adherent at one or two points, or over a small area. But in by far the larger number of cases, when the inflammation has been

general, the absorption of the fluid and the coming together of the inflamed surfaces end in their more or less complete coalescence, and in the obliteration in an equal degree of the pericardial cavity. The characters which the resulting adhesions display depend largely of course upon the quality and quantity of the false membrane from which they have arisen. Sometimes they are thin and delicate, and differ little from ordinary connective tissue. Sometimes they are thick, fibrous, and perhaps œdematous, and then measure maybe  $\frac{1}{4}$  or  $\frac{1}{2}$  an inch or more in thickness. Sometimes they are almost cartilage-like in density and hardness; and they may become the seat of calcareous formations, constituting bands or patches of considerable extent.

In the course of pericarditis other results besides those which have been enumerated may take place. In some cases the newly-formed blood-vessels of the false membrane become ruptured, and blood is effused into its substance, or (if the opposed surfaces be not yet adherent) into the pericardial cavity. This hemorrhage may be so copious as to cause death. In other cases the inflammation becomes suppurative, and the pericardial cavity is converted into an abscess which may ultimately contain two or three pints or more of pus. Suppurative pericarditis is often very chronic in its progress; and sooner or later the pus may point and discharge externally in the præcordial region, or extend in other directions beyond the limits of the pericardium.

The inflammatory processes of pericarditis, when the attack is slight, are probably limited to the serous membrane; but, when the inflammation is intense or assumes a chronic form, it invades the deeper tissues, which then get congested and œdematous, and often, if muscular, degenerated and enfeebled. Hence the integuments of the præcordial region become in many cases distinctly œdematous; and it is perhaps occasionally owing to involvement and consequent enfeeblement of the intercostal muscles that the intercostal spaces are observed to bulge. It is a more important fact that, in a large number of cases, the outer layers of the muscular walls of the heart become to a greater or less depth obviously degenerated, softened, and weakened.

*Symptoms and progress.*—The symptoms of pericarditis are so commonly associated with those of the malady in the course of which it arises, and with those of endocarditis, which is so often developed in common with it, that it is not altogether easy to disentangle them entirely from those belonging to these other conditions. Pericarditis is in many cases so mild a disorder that it is attended with few or no symptoms of any importance. In other cases it is one of the most perilous maladies with which we have to deal, and its symptoms are correspondingly severe. But, between these extremes, cases of all grades of intensity are met with.

In its mildest form, pericarditis often escapes detection, or is recognised only by the accidental discovery of pericardial friction; in most such cases, however, there is at some time or other slight præcordial pain or uneasiness, together with extension of cardiac dulness, and febrile dis-

turbance. Most cases of what are termed 'latent' and 'dry' pericarditis belong to this group.

In describing the symptoms of more aggravated cases of pericarditis, it will be convenient to divide them into local and general, and to discuss these *seriatim*. The local symptoms are due directly to the condition of the pericardium and its influence on surrounding parts. The patient generally complains of pain and tenderness in the region of the heart. He winces if pressure be made over the præcordium, and still more if it be made in the epigastric region. The pain varies in character, is aching, cutting, burning, or a mere sense of soreness, and occasionally extends from the heart to the left shoulder and down the left arm. It is usually augmented by movement of the diaphragm, and hence the patient tends to breathe rapidly, shallowly, and with little abdominal motion. When the pain and tenderness are very severe, he usually lies upon his back, and, while moving his limbs with tolerable freedom, keeps his trunk almost entirely still. The roughening of the pericardial surface which takes place at the commencement of the disorder is attended with distinct friction-sound, the characters of which have already been described. This usually commences at the base, or along the right side, occasionally at the apex, but soon becomes general; and having lasted for an uncertain time (a few hours, a day or two, or longer) slowly or rapidly vanishes. The further progress of the case will alone determine whether this disappearance is due to adhesion having taken place, and is therefore permanent, or whether it depends on increase of fluid effusion and consequent separation of the pericardial surfaces from one another. In the latter case, the friction recurs with the absorption of the fluid, and its final disappearance, due to adhesion, is a subsequent event. Pericardial friction-sound is usually rendered more intense and at the same time modified in character by the application of pressure to the præcordium; and its intensity is often distinctly influenced by the movements of respiration. It may be added that pleuritic sounds developed along the edges of the præcordial region often have a distinct cardiac rhythm impressed upon them. Other phenomena which may often be observed are: œdema of the integuments over the cardiac region; a perceptible thrill, arising from the grating of the two rough pericardial surfaces upon one another, to be felt by applying the open hand to the cardiac area; and more or less complete masking of the normal heart-sounds by those of pericardial friction. It is scarcely necessary to say that all the phenomena (local and general), which have been previously described as belonging to pericardial effusion, are commonly added during the progress of the disease to those which have now been detailed, and indeed that they constitute an essential element in the clinical description of pericarditis.

The influence of pericarditis on the action of the heart and on the pulse is various. Early in the disease the heart itself may be little affected; more commonly its movements are increased in frequency, and the pulse is at the same time harder and fuller than natural. With the increase of effusion the beats of the heart become accelerated, and diminished in

strength ; the pulse consequently gets small and feeble, and often irregular. Moreover, its rate is apt to be increased by any slight excitement or muscular effort.

Among the general symptoms referrible to pericarditis are the following : first, those of inflammatory fever, namely, increase of temperature, dryness of tongue, thirst, loss of appetite, and scanty, high-coloured urine ; second, shortness of breath, often amounting to dyspnœa, or orthopnœa, and frequent short, hacking cough ; third, vomiting, a general aspect of distress, a look of anxiety, with pinched features and a pallid, or sometimes congested, countenance, weariness, want of sleep, tossing of the arms, irritability, rambling, and occasionally (especially towards the close of fatal cases) maniacal delirium, convulsions, or coma. The latter phenomena, however, which are certainly not unfrequently associated with pericarditis, seem almost always to have been observed in cases where the pericarditis was distinctly rheumatic, and where, therefore, it is possible that they may have been due to some other cause. Tetanic spasms and risus sardonicus also have occasionally been noticed in rheumatic pericarditis. Further, in cases attended with much effusion, difficulty of swallowing from pressure on the œsophagus, congestion of the head and neck from obstruction of the superior cava, and aphonia from compression of the left recurrent laryngeal, have been observed.

Recovery from simple pericarditis is attended with the gradual subsidence of the symptoms which belong to the disease. In slight cases convalescence is often rapid and complete. Generally, however, when there has been much pericardial effusion, and the symptoms have been severe, the amendment is slow ; and permanent ill-health is apt to remain. Pain, tenderness, cough, difficulty of breathing while the patient is at rest, and fever, gradually subside, the patient's appetite improves, and he begins to enjoy refreshing sleep. But the pulse frequently remains for a long while preternaturally quick, or, on the other hand, becomes slow and intermittent, and the præcordial prominence and increased dulness still continue excessive. Moreover, under these circumstances the patient often remains incapable of taking active exercise on account of the persistent ready development of cardiac uneasiness, palpitation, and shortness of breath. These symptoms also may in their turn subside more or less completely. Pericardial friction occasionally persists for months.

Adhesion of the pericardium can rarely be diagnosed with certainty in the absence of a distinct history of pericarditis. It is often attended, however, with persistence of enlarged area of dulness, and permanent and unalterable elevation and displacement outwards of the apex-beat, together perhaps with palpitation, dyspnœa, and some of the general symptoms of cardiac disease. Other occasional diagnostic indications (which, however, are not special to adherent pericardium) are, retraction at the apex and of the præcordial intercostal spaces during the ventricular systole, and an impulse corresponding to the diastole. Moreover, a pericardium which has once been inflamed is apt, under the influence of exciting causes,

again to become inflamed, notwithstanding the complete obliteration of its cavity.

Pericardial suppuration generally takes a chronic course. The commencement of suppuration may be attended with rigors and elevation of temperature. The former may recur from time to time ; the latter probably continues ; and generally the fever assumes a hectic type. The local phenomena are not always very well marked ; there will probably be some persistence or increase of pain and tenderness, gradual extension of præcordial dulness, and augmenting distension of the præcordial region, with distinct and increasing œdema of the integuments,

Severe pericarditis not unfrequently ends sooner or later in death. If death occur during the height of the disease it may be the result of one or other of the cerebral complications which have been enumerated, or of asphyxia due to pulmonary complication ; but in the majority of cases it is the consequence either of slow asthenia or of an attack of syncope. When death takes place at a later period, it is not unfrequently dependent on the gradual supervention of the ordinary consequences of heart disease—namely, pulmonary congestion with pulmonary apoplexy, or systemic venous congestion with anasarca, and affection of the liver, kidneys, and other organs. Suppurative pericarditis is generally fatal.

### B. *Myocarditis*

*Causation and morbid anatomy.*—Inflammation of the muscular tissue of the heart rarely occurs except in connection with peri- or endo-carditis. In pericarditis, as we have already pointed out, the muscular walls in contact with the inflamed serous membrane are often distinctly implicated ; and there is no doubt that their inner aspect may be similarly involved during the course of an attack of endocarditis. It may even happen that in some situations they become thus affected in their entire thickness. Occasionally, no doubt, idiopathic inflammation arises, independently of inflammation of the serous membranes. It is said then to occur chiefly on the left side and towards the apex. It may, however, be general. Sometimes pyæmic abscesses, or abscesses due to embolism, are found studding the muscular substance. These are mostly small. But abscesses of considerable bulk have been described.

Myocarditis presents the same pathological phenomena as inflammation of muscular tissue elsewhere. The affected parts become injected, there is a tendency to proliferation of the stationary protoplasmic elements, and to the escape of leucocytes and red corpuscles ; and in connection with these phenomena the muscular fibres rapidly lose their striation, become granular and opaque, and break down. Not infrequently indeed this affection of the muscular fibres, together with irregularly distributed mottling and softening of tissue, is the only obvious indication of myocarditis.

The early effects of inflammation are to diminish the cohesion of the affected tissues and to render them less resistant than natural. But sub-

sequently, if resolution do not take place, they become contracted and hardened, and assume a cicatricial character. Under either of these conditions, especially if the morbid processes be circumscribed, yielding of the affected walls may take place, and the foundation of cardiac aneurysm be laid. When abscesses form they may burst into the pericardium, exciting inflammation of that membrane; or into the cardiac cavities, and thus evoke the phenomena of embolism or pyæmia. In many cases, no doubt, the inflamed muscle becomes completely restored.

*Symptoms and progress.*—It is impossible to assign any specific symptoms to myocarditis. Among those most likely to be present, are; fever; debility of the heart with feebleness of impulse of first sound, and of pulse; tendency to faint; difficulty of breathing, with oppression and uneasiness in the præcordial region; and nervous phenomena such as restlessness, giddiness, delirium, convulsions, and coma. Death usually occurs suddenly from collapse or syncope.

### C. Endocarditis

*Causation.*—The causes of inflammation of the lining membrane of the heart's cavities are to a large extent identical with those which excite pericarditis and myocarditis. Most of the local causes, however, to which pericarditis may be due, can scarcely be operative upon the endocardium. Endocarditis is occasionally the result of the accidental rupture of valves, or chordæ tendineæ; more commonly it depends on exposure to cold; but by far its most frequent cause is the presence of rheumatism. It may also be caused by extension from abscesses in the muscular parietes. Again, like pericarditis, it is often developed in connection with chorea and scarlet fever. A chronic form of endocarditis also may occur in relation with the syphilitic cachexia, chronic alcoholism, Bright's disease, and other affections inducing persistent dyscrasia.

*Morbid anatomy.*—In the great majority of cases endocarditis is limited to the left side of the heart, and to the valves or their immediate vicinity. Its presence is indicated by increased vascularity of the affected area; infiltration and inflammatory overgrowth of tissue, and consequent increase of thickness; and development of warty growths or granulations upon the surface. The thickening, which is mostly attended with opacity and softening, varies in degree, and, when it involves the thin curtains of the valves or the delicate chordæ tendineæ, causes them to become puckered or contracted. The granulations are in the first instance mere points; but they soon increase in size, sometimes becoming small bead-like bodies, sometimes papillary excrescences, sometimes rounded masses from the size of a tare up to that of a filbert. Frequently neighbouring outgrowths coalesce, forming warty, botryoidal, or cauliflower-like masses, and in some cases pendulous fringe-like but irregular processes, which may attain a length of one or two inches. During the inflammatory process it is not uncommon for ulceration to take place. If this affect the valves it leads to their partial detachment, to their attenuation at

points, and the production of valvular aneurysms, or to their perforation; if it involve the tendinous cords, to their laceration.

When inflammation attacks the aortic valve the granulations which characterise it first appear as a fringe along the festooned inner margins of the lunulæ, but with the extension of disease they may cover the whole of the under surface of one or more of the cusps and even extend downwards on to the septum. They often, indeed, at length hang from the free edge of the valve, which then usually is thickened, contracted, and irregular in form. The aortic aspect of the valve is rarely the seat of granulations.

When the mitral valve is inflamed, granulations appear on its auricular aspect a little within the free edge, whence they may extend over the greater part of that surface and thence on to the auricular walls. With the development of granulations there is usually thickening and contraction of the free edge of the valve, and at the same time some contraction of the valve at its base, in virtue of which the orifice becomes diminished in capacity. The chordæ tendineæ also are apt to be the seat of granulations, to undergo thickening and shortening, and to become blended to a greater or less extent with the valvular curtains. Granulations are rarely met with on the ventricular surface of the valve.

Inflammation, when it attacks the valves on the right side of the heart, produces exactly similar effects to those above described.

Inflammation of the endocardium is not always acute, or always limited to the valves. In regurgitant aortic disease the surface of the septum ventriculorum, for half an inch or an inch below the valve, generally presents cicatricial thickening, and occasionally marked contraction. The thickening is the result of chronic inflammation, probably due to the constantly recurring impact of the reflux blood-stream against the ventricular walls in this situation. Again, we occasionally find, especially in connection with some forms of so-called 'atheroma' of the arteries, the lining membrane of the left ventricle studded with irregular patches of opaque thickening. These are due to hypertrophy, with degeneration, of the endocardium, and are doubtless also of inflammatory origin.

*Symptoms and progress.*—The symptoms of endocarditis, apart from those of the disease (if any) with which it is associated, and of the lesions to which it gives rise, are neither striking nor serious. The symptoms, indeed, which are usually ascribed to this affection are mainly made up of those of acute rheumatism and valvular obstruction or incompetence. And it must be admitted that it is by the development of the valvular lesions, which are an almost invariable accompaniment of endocarditis, that we mainly assume its presence and trace its progress. It is needless to say that the discovery of valvular mischief is no proof of the presence or even of the pre-existence of endocarditis. But if, in the progress of any one of those diseases of which endocarditis is a common complication, we detect a cardiac murmur which had not previously existed; and if further observation proves this to be a permanent phenomenon; or if changes in it indicative of increasing mischief take place; or if additional murmurs become developed, we cannot reasonably

doubt that endocarditis is present. The same conclusion may be fairly arrived at when a young person, who is known to have been hitherto healthy, presents vague symptoms of ill-health, and reveals under the stethoscope a newly developed and persistent valvular murmur. It is very important, however, to note that, in forming a judgment with respect to cases of this kind, there are many sources of fallacy to be avoided. We must be careful that we do not mistake a pericardial rub for an endocardial murmur; that we do not hastily assume that a murmur which we hear for the first time has not existed from some previous attack of rheumatism, or from birth; and that we do not take a functional or hæmic murmur for one of organic origin. On the other hand, we must not too readily take it for granted that, for example, in a case of rheumatism in which the heart is known to have been injured in some previous attack, the cardiac disease which we recognise is all of old date; we must not forget that direct murmurs due to granulations occasionally disappear; and, further, we must always recollect that inflammatory vegetations may be formed on the valves, and more particularly on the auricular aspect of the mitral, which never impair the action of the heart and never give rise to abnormal sounds.

The remaining indications of the presence of endocarditis are slight and fallacious. From the position of the inflamed areae it is scarcely possible that præcordial tenderness should be present; and, indeed, it is rarely if ever observed. Uneasiness or pain in the region of the heart may, however, be complained of. From the smallness of the extent of the inflamed surface we should scarcely expect much febrile disturbance; nor, as a rule, is simple endocarditis attended with marked fever. Still, there may be elevation of temperature, thirst, scanty urine, and other indications of the febrile condition. Again, here as in pericarditis, we may naturally look for some excitement or other modification of the action of the heart. It generally acts more frequently and more powerfully than natural.

The prognosis of endocarditis is very serious. It is rare for perfect recovery to take place. Moreover, the patient remains, for the most part, liable to fresh attacks of inflammation, and consequent increase of valvular lesion. The results of endocarditis are mainly those which have already been considered under the head of valvular disease, and will, of course, vary according to the valve affected, and the degree and kind of its affection, and need not be again discussed. But it must not be forgotten that it is in connection with endocarditis and its local consequences, far more than with any other form of disease involving the endocardium, that detachment of solid particles or masses takes place which are conveyed as emboli to the brain, liver, spleen, kidneys, lungs, and other organs; and that the liability to this detachment has little or no obvious relation with the severity of the cardiac lesion. The subject of embolism will be fully discussed farther on.

*D. Treatment of Inflammation of the Heart and Pericardium*

In most cases of the several forms of cardiac inflammation which have been passed in review, the affection is developed in the course of other diseases, such as rheumatism, Bright's disease, and pyæmia, for which the patient is already under observation. The treatment of these maladies, therefore, forms an essential element in the treatment of the heart-affections which complicate them. It is important, however, to consider whether any, and if so what, additional measures may be adopted in reference to the cardiac lesions.

In the treatment of pericarditis the abstraction of blood is generally regarded as a most important remedial measure. Blood may be taken by venesection from the arm; but it is probably most conveniently, and best, removed from the præcordial region by cupping or leeching. To be efficacious, bloodletting should be performed early, while the symptoms are yet acute; and should be, so far as is compatible with the patient's age and condition, free, in order to obviate as much as possible the necessity for its repetition. A dozen or twenty leeches may be applied to the chest of an otherwise healthy adult, and the bleeding subsequently encouraged by fomentations or poultices. In slight cases at an early period, and in severe cases after removal of blood, counter-irritation is of considerable value. It relieves pain and uneasiness, and probably promotes the absorption of fluid. A large mustard plaister, or cotton-wool saturated with turpentine or spirits of wine, and covered with some impermeable tissue, may be applied to the præcordium; or iodine paint or blistering fluid may be painted over the part; or simple fomentations, as hot as the patient can bear them, may be persisted in. There is, it may be observed, a practical objection to the use of applications which blister the surface: namely, that they interfere with that frequent examination of the cardiac region which is so important. Of the value of opium in this, as in almost all other inflammatory affections, there can be no doubt. It may generally be safely administered, and in large doses; excepting, perhaps, when the heart shows signs of great enfeeblement, when the circulation is embarrassed, the respirations rapid and shallow, and the skin dusky. When these latter phenomena supervene, ammonia, ether, alcohol, and other stimulants are indicated. In order to reduce inflammation, and remove the products of inflammation, it was formerly deemed essential to put patients under a course of mercury or iodide of potassium. These remedies, however, are probably inefficacious except in certain constitutional conditions. Again, diuretics and purgatives have been largely advocated for the purpose of removing fluid accumulations from the serous cavities. But there is little proof that they have any appreciable influence in this respect. It may, nevertheless, be useful when febrile temperature is present to employ some of those agents (namely, aconite, quinine, or antifebrin) which are known to reduce temperature. But the most efficient means of effecting the removal of dropsical accumulations is to improve the patient's general health. And on this and other grounds

it is always important to bring him under the influence of tonic treatment as soon as the condition of the digestive organs allows of its employment.

The above remarks as to treatment relate more immediately to pericarditis. But they are to some extent applicable to endocarditis. It must be borne in mind, however, that local bleeding and local medication of all kinds are necessarily less efficacious in endocarditis than in the other affection; and, further, that as endocarditis is (except in its remote consequences) a less dangerous and severe affection than pericarditis, it generally needs a less active plan of treatment.

When, in pericarditis, the accumulation of fluid appears to be seriously interfering with the action of the heart, especially if it persist despite all treatment; or when we have reason to suspect the presence of pericardial suppuration; the question whether paracentesis should be performed for the removal of the fluid will perforce present itself. The operation is one which has been performed neither frequently nor with much success; moreover, it is an operation of considerable delicacy and difficulty; still, it can scarcely be doubted that it should be attempted under the above circumstances. The chief danger to be avoided is that of puncturing the heart, the next that of wounding the internal mammary artery. To avoid the former danger it is important first to determine accurately the lateral boundaries of the distended pericardium, and next to satisfy oneself, by the presence or absence of sensible impulse, over what area (if any) the heart is in contact with the anterior thoracic parietes, and then carefully to make an opening into that part of the pericardium from which the heart seems to be remote. The mammary artery runs down behind the costal cartilages, a little outside the sternum. The most eligible spot for puncture is usually towards the inner extremity of the fourth or fifth intercostal space close to the sternum. It is probably the safest plan to divide the soft tissues with the scalpel one by one until the parietal layer of the pericardium is reached, and then to puncture carefully with a fine trocar and cannula. If serum escape, the entrance of air should be prevented; if pus, it may be advisable to wash out the cavity, and even to inject a weak solution of chlorinated soda or Condy's fluid. In some cases it may be well to make a preliminary puncture with a fine aspirating needle.

---

### III. MORBID GROWTHS AND PARASITES

#### A. *Fatty Growth*

The presence of a small quantity of fat upon the surface of the heart, mainly in the course of the transverse and longitudinal sulci, is extremely common, especially in persons who have attained middle life, or who present a general accumulation of fat throughout their connective tissue. This condition is of no importance. But occasionally, in persons of great obesity, fatty growth becomes excessive and encroaches seriously upon the substance of the heart, not only investing the organ, but invading the substance of its walls, separating the muscular fibres from one another,

and imparting to the walls in places (more especially in the right ventricle) the softness and general aspect of simple fat.

The *symptoms* referrible to this affection (which is sometimes described as a form of fatty degeneration) are those of cardiac feebleness and incompetence.

#### B. *Tubercle*

Tubercle is of infrequent occurrence, and generally takes place in connection with widespread distribution of the disease. Miliary tubercles are occasionally found imbedded in the substance of the muscular walls. Their most common seat, however, is the pericardial serous membrane. In this situation they may occur in small scattered groups only, or may be thickly and pretty generally distributed; and, especially in the latter case, are often associated with more or less abundant inflammatory exudation. Cheesy tubercle in considerable masses, and generally associated with thick and dense adhesions, is also occasionally observed in the pericardium.

The *symptoms* of cardiac and pericardial tuberculosis are generally lost in those of more advanced tubercular disease of other organs. If, however, they be sufficiently pronounced to attract attention, they are indistinguishable from those of subacute or chronic pericarditis.

#### C. *Syphilis*

Syphilitic affection of the heart is not uncommon. The condition now generally regarded as such is characterised by the presence of fibroid infiltration, of greater or less extent, of the cardiac walls; with imbedded caseous masses, closely resembling the so-called 'knotty' tumours of the liver; and with more or less indurated thickening and adhesion of the pericardium. True gummata of recent formation have also been observed. Microscopically, the diseased tissues present, as do those of gummata developed in voluntary muscles, overgrowth of the interstitial connective tissue, with fatty or caseous conversion of certain parts, in which the involved muscular fibres share. The disease may implicate any part of the heart, but most commonly affects the ventricular walls. Sometimes it forms tumours, which project from the outer aspect of the heart, or encroach upon its cavities; sometimes it leads to thinning of certain parts, and to aneurysmal dilatation. But fibroid change of the cardiac walls may be due to other causes than syphilis, to chronic inflammation for example; and the specific origin, therefore, of all such cases must not be hastily assumed.

The conditions here spoken of may, at any rate from the clinical point of view, be combined. They are chronic in their progress; and are not unfrequently associated with adhesion of the pericardium, lesion of the valves, and hypertrophy, dilatation, or other modifications of the walls or cavities of the heart. The symptoms, therefore, which they induce, although liable to considerable variety of detail, are essentially those of chronic heart-disease, and mainly of those conditions or stages of disease in which the heart is enfeebled and incompetent to carry on the circulation effi-

ciently. Dropsy is of common occurrence, and sudden death not unfrequent. The disease occurs almost exclusively among persons of middle or advanced age.

#### D. *Malignant Disease*

This affects the pericardium, as it does other serous membranes, only much less frequently. It may occur here in the form of miliary granulations, lenticular plates, or nodulated outgrowths. It is almost without exception secondary, and probably never attains sufficient proportions to cause obvious symptoms. Malignant disease of the muscular walls of the heart is also not common, and is probably always of secondary origin. Generally it occurs there in the form of small imbedded tumours, which are of no practical importance. Occasionally, however, it forms masses, as large as a hen's egg or orange, which encroach on the cavities or orifices of the heart, and constitute a serious impediment to the circulation. In some instances, sarcomatous and other growths, originating in the posterior mediastinum, involve the heart by continuity: they steal, as it were, along the vessels at the base, and then gradually infiltrate the muscular parietes of the auricles and ventricles, separating the muscular fibres from one another, and causing general increase of thickness. In these cases no tumours may be developed, and microscopic examination may be needed for the detection of the nature of the morbid process which has been going on. Among the varieties of malignant disease which have been found involving the heart and pericardium may be mentioned scirrhus, encephaloid, melanotic cancer, epithelioma, lymphadenoma, and sarcoma.

Malignant disease of the heart and pericardium has rarely, if ever, been diagnosed during life, and indeed rarely gives evidence of its presence by symptoms referrible to the heart. It is obvious, however, that the symptoms to be looked for are those indicative of cardiac obstruction and weakness, and that the supervention of such symptoms in the progress of malignant disease might suggest the possibility of cardiac involvement.

#### E. *Parasites*

These are seldom met with in connection with the heart. The *trichina spiralis* has never been found in it. The *cysticercus cellulosæ* has been discovered there, but not as productive of symptoms. *Hydatid* tumours also have occasionally been observed, varying from the size of an orange downwards, and either imbedded in the substance of the muscular walls, or occupying the subserous tissue of the visceral pericardium.

The *symptoms* to which hydatids would give rise are those: either of interference with the due performance of the cardiac functions; of supuration, to which such cysts are liable; of pericarditis, dependent on extension from the inflamed cyst, or on its rupture into the pericardium; or, lastly, of the discharge of the hydatid contents into the interior of the heart.

#### F. *Treatment*

It is impossible to lay down rules in regard to the treatment of cases in which the heart is involved in adventitious growths or the seat of para-

sites. The symptoms likely to be induced are mainly those of cardiac debility and incompetence; and the treatment must be adapted to the symptoms which are present. It may be said, however, generally, that diffusible stimulants and tonics are indicated.

#### IV. DEGENERATIONS

##### A. Degenerations of the Muscular Walls

*Causation and morbid anatomy.*—We have already pointed out that, under the influence of starvation and various wasting diseases, more especially phthisis, the heart becomes remarkably diminished in bulk. But this change is due to atrophy alone, the muscular fibres undergoing simple attenuation, without structural change.

Of actual degeneration, three varieties are generally described—namely, *fatty* or *yellow* degeneration, *granular* or *brown* degeneration, and *fibroid* degeneration.

1. *Fatty degeneration* in an advanced condition is indicated by softness of the affected tissues, opacity, a peculiar pale buff colour, and, it may be, obvious greasiness. Under the microscope, the muscular fibres are found to have lost, in a greater or less degree, their natural striation, to be studded with minute refractive oily molecules, and to be, as a rule, more friable than in health. In the early stage it sometimes happens that the oily particles occur only at the poles of the nuclei of the muscular fibres, or arranged in longitudinal strings; but with the progress of the disease they get more numerous; and in extreme cases the fibres lose all their normal characteristics and are converted into opaque, irregular cylinders of accumulated fatty particles.

Fatty degeneration occurs under various conditions. It is frequently the result of inflammation, and, when developed in connection with pericarditis, occurs more especially in the layer of muscular fibres immediately subjacent to the visceral pericardium. It is sometimes observed in acute diseases, especially certain fevers, and in poisoning by phosphorus. We have seen it remarkably developed in a child that died of acute purpura. It is a common condition of advanced life, especially if this be attended with certain diseases or morbid tendencies, such as heart-disease, chronic bronchitis, Bright's kidney, hepatic disease, arterial degeneration, or gout. It is common also, mainly in old age, as an immediate consequence of obstructive disease of the coronary arteries or of any other morbid condition impairing the vitality of certain portions of the organ.

When the degeneration occurs in connection with inflamed serous membrane, the affected lamina appears to the naked eye anæmic, and in other respects but little altered. When it is due to general disease, or to disease influencing the heart generally, the whole organ may become pallid and softened; but more frequently the tissues are mottled with fatty degenerated spots or patches—a condition which is often peculiarly distinct in the *carneæ columnæ* and on the inner surface of the ventricles. When the degeneration is secondary to obstructed arteries, it usually

occupies a circumscribed region which presents, as a rule, remarkable softness and friability.

2. *Granular degeneration* is generally distributed uniformly throughout the muscular tissue of the heart, which assumes a brownish hue. The muscular fibres are studded with longitudinal strings of brownish particles, the exact chemical constitution of which is not known. The circumstances which determine this form of degeneration seem to be the same as those to which general fatty degeneration is also due.

3. *Fibroid degeneration* affects portions only of the cardiac walls, and is comparatively common on the right side. The affected tracts are greyish, dense, and hard—changes which are due in different degrees to overgrowth of fibroid tissue and to wasting of the muscular fibres, and their conversion into, or replacement by, fibroid tissue. The change is probably often undistinguishable from the consequences of syphilis, but is sometimes a sequela of myocarditis. Again, hypertrophy of the heart, and especially the form of it secondary to Bright's disease, is often made up partly of overgrowth of muscular tissue, partly of overgrowth of the intervening connective tissue; and in some cases the latter element becomes disproportionately abundant, and the heart consequently, in a sense, degenerate and enfeebled.

*Symptoms.*—The symptoms of degenerative affections of the muscular walls of the heart are mainly those of cardiac weakness and incompetence; such especially as dyspnoea, lividity, tendency to syncope, indistinctness of the first sound of the heart and weakness of pulse, which may be quick, slow, irregular, or variable. To these must of course be added the other usual consequences of defective or impeded circulation. Enfeeblement from degeneration is one of the recognised causes of sudden death; and it is an important fact that sudden death is liable to occur in those in whom degeneration is not yet far advanced, and who have not yet presented definite symptoms of cardiac disease. Rupture of the heart is not uncommon in those cases in which local softenings from arterial obstruction are present.

#### B. *Degenerations of Valves and Endocardium*

*Causation and morbid anatomy.*—Fibroid, fatty, and calcareous changes, or degenerations, of the endocardium are among the most frequent causes of heart-disease. For the most part they come on with advancing years, and may be regarded (with the corresponding conditions of the arterial system) as some of the chief consequences and indications of senile decay. They are apt, however, to manifest themselves even in early adult life, especially in those who have lived intemperate or over-laborious lives, or have suffered from syphilis, or are the subjects of chronic Bright's disease. They are also apt to supervene on ordinary endocarditis; and hence it is often difficult (except from the history) to distinguish between degenerative lesions of primary origin and such as are the consequences of bygone acute endocardial inflammation. It must be remembered, however, that the changes, which are here roughly grouped

together as degenerations, probably for the most part take their origin in a form of chronic endocarditis—a subject which will be more fully discussed when we come to speak of endoarteritis and degeneration of arteries.

Degenerative changes may manifest themselves at any point of the endocardial surface; but far more frequently involve the valves than other parts. The lining membrane of the left ventricle is more commonly affected than that of the other cavities; and the aortic and mitral valves far more commonly than the valves of the right side. In some cases the valves present simply a few opaque, buff-coloured (atheromatous) patches; in some they manifest general fibroid thickening—a condition which is usually accompanied by contraction, and often by fatty or calcareous deposit; in some cases they are rendered thick, nodulated, and irregular, from the accumulation of combined fibroid, fatty, and calcareous deposit, and then, if the disease be far advanced, project as rigid processes across the orifices to which they belong, become blended to a greater or less extent with one another at their bases, and reduce the valvular aperture to a mere chink; in some cases, again, the degenerate tissue undergoes erosion, excavations form, and finally perhaps the valve gets perforated or ruptured. These changes generally are not strictly limited to the valves; but are apt to be prolonged from the aortic to the aorta or the septum ventriculorum, and from the mitral to the chordæ tendineæ, which become thick, short, and sometimes incorporated with one another. The chordæ tendineæ, like the valves, occasionally get lacerated.

*Symptoms.*—It is obvious that the conditions here described may produce all varieties of valvular defects, singly or in combination; and more especially the same defects that commonly result from acute endocarditis—namely, obstructive and regurgitant disease of the aortic and mitral orifices. The changes are chronic, and the symptoms which they induce creep on insidiously; so that it often happens that a patient has had the disease upon him for years before its presence is distinctly revealed. Indeed, the first clear indication of heart-disease is sometimes due to the sudden rupture of a valve, or some other untoward complication or event; and we are often astonished to find post mortem how extreme a degree of contraction of the aortic or mitral orifice has been compatible, not merely with life, but with life passed in comparative ease and comfort.

The early symptoms of degenerative disease of the valves are usually vague, comprising, perhaps, some degree of irregularity of the pulse, more or less shortness of breath, occasional neuralgic pain or uneasiness in the region of the heart, attacks of giddiness or faintness, and not unfrequently impairment of the digestive functions. But inasmuch as the cardiac affection is usually associated with degenerative changes in the arteries and even in other tissues, the symptoms due to these become mingled with those of the heart-disease, and may to some extent aid our diagnosis of the actual condition of the heart. Among such indications may be mentioned the presence of rigid or otherwise diseased arteries, as revealed by the condition of the pulse or by cerebral symptoms, and the existence of the arcus senilis. The symptoms of the declared disease are

mainly those of the valvular lesions which have already been fully considered. The chief practical point to be remembered is that, however slow the symptoms may have been in attaining serious development, the morbid processes on which they depend are in the nature of things progressive and tend surely to a fatal issue.

### C. *Degenerations of the Coronary Arteries*

The coronary arteries and their branches are liable to all those degenerative changes which affect the lining membrane of the heart and arterial system. Their parietes consequently become thickened with fatty or calcareous deposit, and their channels reduced in size or obliterated. The later conditions involve the imperfect nutrition of the parts to which the affected vessels lead, and induce those localised fatty changes, attended with discoloration of tissue and softening, which have already been adverted to.

No specific *symptoms* can be referred directly to disease of the coronary arteries. Angina pectoris has been asserted to occur with special frequency in these cases. But it must be recollected that arterial degeneration is usually present in persons advanced in years, and for the most part associated with other cardiac degenerations.

### D. *Treatment*

Degenerative conditions of the heart, as of other organs, call for all measures—tonic, alimentary, and hygienic—calculated to maintain or improve the general health; but they also need special precautions and special items of treatment, according to the particular phenomena and dangers which each case presents. These have been sufficiently indicated on an earlier page under the head of the treatment of cardiac derangements.

---

## V. ANEURYSM OF THE HEART

*Causation.*—In addition to that general dilatation of the heart's cavities which has been previously considered, partial dilatations or aneurysms are occasionally met with. They have been oftener observed in men than in women, and for the most part at an advanced period of life. They are not uncommon, however, during middle age, and occur, indeed, though with extreme infrequency, in children.

Localised dilatation obviously depends on comparative feebleness of that portion of the cardiac wall which undergoes dilatation, and its inability to resist successfully the internal pressure to which it is subjected. The cause of weakness is doubtless different in different cases. In some, dilatation seems to arise in ulcerative destruction of the lining membrane, or in laceration and breaking down of more or less of the muscular wall; but in most it is apparently due to the presence of one of those forms of enfeeblement which have just been passed in review, namely, fatty, fibroid, or some other variety of degenerative change. It is obvious, therefore, that it may be a consequence of endocarditis and myocarditis, in either

their acute or their chronic forms, and of syphilis. Not improbably also it occasionally originates, as do arterial aneurysms, in the effects of violent muscular exertion or of violence inflicted from without.

*Morbid anatomy.*—Cardiac aneurysms now and then occur in the right ventricle and even in the left auricle, more especially at the foramen ovale; but by far their most common seat is the left ventricle. They are generally said to affect chiefly the apex of this cavity; but they may originate at any spot within it. In size they range from that of a pea to that of the heart itself. In form they may be: a simple hemispherical expansion of the apex or some other part; or flask-like, communicating by a comparatively small orifice with the ventricular cavity; or sacculated, consisting of a series of intercommunicating chambers imbedded in the substance of the walls, and extending over a more or less considerable area. Their parietes vary in thickness, and are sometimes as thin as paper; and generally (especially if the aneurysm be of large size or old date) consist of dense fibroid material, with little or no trace of muscular tissue. Occasionally they undergo calcification. Cardiac aneurysms sometimes are empty, sometimes contain laminated or other forms of coagulum. As regards their results, they seem occasionally, after having reached a certain size, to remain stationary, or nearly so; but they tend ultimately to undergo laceration, and thus to cause communication between the left ventricle and one or other of the auricles, the right ventricle or the pericardium. In their progress towards the surface they not unfrequently cause pericardial inflammation, and adhesions, which both delay rupture and limit its effects.

Among cardiac aneurysms must be included those of the valves and coronary arteries. Valvular aneurysms occur chiefly in the aortic and mitral valves, but occasionally in the tricuspid, as the result of inflammatory or degenerative weakening or erosion; and they constitute bulgings of various sizes, which, in the case of the aortic valve, project into the ventricle, in the case of either of the auriculo-ventricular valves into the auricle, and usually sooner or later rupture, and thus allow of free regurgitation.

Aneurysms of the coronary arteries are rare. They are generally developed in the trunks at a short distance from the aorta, and form small tumours in the transverse sulci. Occasionally numerous small aneurysms stud not only the trunks, but also many of the larger branches. Like cardiac aneurysms, they may open into the pericardium, cardiac cavities, or large vessels at the base of the heart.

*Symptoms.*—Cardiac aneurysms for the most part are never suspected to be present until the occurrence of rupture causes either grave symptoms of cardiac disease, or death from escape of blood into the pericardial cavity. There are no special symptoms by which their presence is indicated. They are of course frequently attended with some of the usual symptoms of chronic heart-disease; and when large and so situated as to come into relation with the anterior thoracic parietes, the presence of a pulsating tumour distinct from the heart may occasionally be recognised.

## VI. RUPTURE OF THE HEART. EFFUSION OF BLOOD INTO THE PERICARDIUM

*Causation.*—Perforation of the muscular walls of the heart may be due to accidental or other violence ; with such cases, however, the physician has little or nothing to do. Spontaneous rupture is an affection almost exclusively of advanced age ; it sometimes occurs in the floor of an aneurysm, sometimes in a heart generally weakened by degenerative changes, but more frequently in a circumscribed patch of softening, due to atheromatous disease and obstruction of the artery which supplies it ; and it is generally immediately traceable to some muscular effort or mental disturbance. Men are more liable to it than women.

*Morbid anatomy.*—Spontaneous rupture occurs almost without exception in the walls of the left ventricle, and mostly in front. It generally forms in the direction of the muscular fibres an irregular rent, or series of rents, which pass irregularly through the walls, and present considerable differences of size, form and position, on the inner and outer surfaces respectively. The lacerated tissue, moreover, is generally infiltrated to a greater or less extent with blood. The consequences of laceration of the heart, though in all cases death ultimately ensues, present a good deal of variety. In some instances (especially in cardiac aneurysm) the actual rupture into the pericardium is preceded by the formation of pericardial adhesions ; in some the rupture occurs primarily into the connective tissue beneath the visceral pericardium ; in both of which cases the effusion of blood is at first circumscribed, and the patient may sink, not suddenly from copious hemorrhage, but slowly with the symptoms of pericarditis. In some instances the rupture occurs directly into the pericardial cavity, and rapid escape of blood takes place into it. The pericardium is then found post mortem to be distended with blood—partly serum, partly a bag of undecolorised coagulum in which the heart is enclosed, and by which it is concealed ; the heart, moreover, is found empty, flattened, and wrinkled on the surface, as if it had been subjected to considerable pressure.

*Symptoms and progress.*—The symptoms of rupture of the heart are far from uniform. In a large number of cases the patient is attacked with severe pain in the region of the heart, gasps for breath, faints, and dies in the course of a few minutes, or even a few seconds. In some cases he is also attacked with sudden severe cardiac pain, faintness, and dyspnoea, but rallies to some extent ; and then, passing into a condition of extreme collapse, attended with remarkable feebleness of pulse, coldness of extremities, profuse sweats, anxiety and restlessness, sighing respiration or extreme dyspnoea, and great oppression, constriction, or pain at the chest, dies at the end of some hours. In some cases again (and these are they in which adherent pericardium or other circumstances delay or prevent the impletion of the serous cavity with blood) the symptoms which mark the occurrence of laceration subside, and the patient returns apparently to a state of more or less complete health ; upon which, at the end of a few

hours, or perhaps a few days, either sudden death occurs from the discharge of blood into the pericardium, or pericarditis becomes developed, and sooner or later carries him off.

The phenomena which attend the rupture of aortic aneurysms into the pericardial cavity are identical with those which have just been described.

*Other ruptures of the heart* besides those of its outer muscular walls may take place; thus, either the septum of the ventricles or that of the auricles may become perforated, the muscoli papillares or chordæ tendineæ may be broken, or the aortic, mitral, or other valves torn from their attachments or split. Such lacerations occur spontaneously probably in those cases only in which there has been previous weakening from disease. The aortic valve chiefly suffers in this respect, and the tendinous cords of the mitral. The consequences of these lesions are obvious: in the first two cases, a communication will be established between the auricles or ventricles; and in the others regurgitation of blood from artery into ventricle, or from ventricle into auricle will be set up or augmented. The symptoms here will be mainly those of advanced valve-disease; and the nature of the accident on which they depend may possibly be diagnosed, partly by the sudden occurrence or aggravation of the patient's symptoms, partly by the circumstances under which this sudden occurrence or aggravation took place, and partly by auscultatory signs.

---

## VII. HYDRO-PERICARDIUM

Dropsy of the pericardium, like hydrothorax or ascites, is one of the incidents of general dropsy. It may depend also on local causes, such as obstruction of the coronary veins, and the growth of tubercles or cancer. A greater or less degree of it is of common occurrence. The amount of serous fluid present rarely exceeds half a pint, and is often not more than one or two ounces. It is insufficient, indeed, as a rule, to cause obvious symptoms or to be discoverable during life. Hydro-pericardium, however, like other varieties of dropsy of serous cavities, may become excessive, and hence not only embarrass the movements of the heart, but reveal its presence by the physical indications (which have already been discussed) of fluid accumulation in the pericardial cavity. When, however, it becomes thus extreme, there is generally reason to suspect its association with some degree of pericardial inflammation.

Hydro-pericardium rarely, if ever, demands special treatment. Counter-irritation of the præcordial region, and the treatment of the condition on which the dropsy depends, are the chief measures to be adopted. It is conceivable that paracentesis might be needed.

---

## VIII. SYNCOPE

*Causation.*—The ætiology and symptoms of syncope have been discussed in an earlier part of this work, to which we refer the reader. With reference, however, to the heart's share in its production we may make a few additional observations here. The cardiac failure (which always takes place to some extent) is commonly referrible to causes, mental or physical, operating through the nervous system; the heart becomes more or less completely paralysed, and contracts feebly or not at all upon its contents. In some cases, however, its failure to act depends upon the presence of some mechanical impediment to its action, as when it is compressed by rapid serous effusion into the pericardium, or by the escape of blood into that cavity, or as when sudden obstruction of one of the cardiac orifices by a clot or embolus takes place, or the patient is suffering from obstructive valve-disease. Hearts enfeebled either by dilatation or by fatty or other forms of degeneration or by abundant or dense pericardial false membranes, are especially liable to failure of action, and are necessarily more liable than others to suffer under the influence of those causes of failure which have been previously enumerated.

*Treatment.*—A patient suffering from syncope should be placed in the horizontal position, all ligatures should be removed from the neck and elsewhere, and he should be freely exposed to cool fresh air. Ammonia, or other such stimulants, should be held to the nostrils; ammonia, ether, or alcohol administered by the mouth; or, if they cannot be swallowed, these or turpentine should be given in the form of enemata; cold water should be dashed in the face, either from a jug or by means of a wetted cloth or towel, and sinapisms applied to the epigastrium and to the limbs. If death seems imminent, it is important to promote the action of the lungs and heart by frictions, and it may be necessary to employ artificial respiration, to stimulate the heart by galvanism, to inject subcutaneously 15 or 20 minims or more of ether or of brandy, or even, if the veins be distended, to bleed from the external jugular vein. If syncope be the result of profuse hemorrhage, the question of transfusion naturally arises. Whenever the syncopie condition assumes a chronic form it is important to maintain the bodily temperature and to prevent the patient from making any kind of exertion. Then, too, the gradual improvement of the patient's vital powers by the judicious exhibition of nourishment, and the assuagement of vomiting, and all other symptoms which tend to impede this improvement, become objects of the highest importance. The value of iron and other tonics in promoting restoration to health, and of opium or chloral hydrate in remedying sleeplessness, excitement, or delirium, need scarcely be insisted upon.

---

## IX. PALPITATION. RECURRENT PALPITATION

*A. Palpitation*

The phenomena of palpitation, so far as they involve the heart and vessels only, have already been adverted to. They comprise increased frequency of cardiac action, suddenness of impulse, together with, not unfrequently, some irregularity or intermission.

The symptoms which attend palpitation are throbbing of the heart and arteries, noises in the ears, *muscæ*, giddiness, faintness, hurried respiration, præcordial uneasiness and anxiety, flushing of face, coldness of extremities, clamminess of surface, together with which are often associated rushing sounds or murmurs at the cardiac orifices, in the larger arteries, and even in the larger veins of the neck.

The conditions under which palpitation occurs are very numerous. Among them may be mentioned: mental excitement; excessive bodily exertion; indigestion; the influence of certain articles of diet or luxury, more especially strong tea and tobacco; anæmia and debility, however produced; hysteria; gout; and, besides these, the presence of actual cardiac disease. In many of the cases here enumerated the palpitation is occasional only, and disappears wholly with the removal of the condition on which it depends. But sometimes it assumes a chronic character. The heart is then apt to get dilated and hypertrophied; and these very changes tend to maintain or aggravate the conditions out of which they arose.

*B. Recurrent Palpitation*

*Definition.*—We have ventured to give the above name to an affection characterised by suddenly beginning and suddenly ending attacks of extremely rapid action of the heart, of variable duration, recurring at irregular intervals, and seemingly unconnected or not necessarily connected with organic disease of the heart or any other viscus.

*Causation.*—The first case of ‘recurrent palpitation’ was, so far as we know, published by Dr. R. P. Cotton.<sup>1</sup> Some two or three other cases were described shortly afterwards; and several also have come under our own observation. So far as our knowledge goes, the affection is one of adult life, and not peculiar to either sex, and seems not only to arise independently of structural disease, but to have no connection with either hysteria or any other functional nervous disorder. Its causation is obscure, but it seems occasionally to be induced by overwork, anxiety, or over-excitement, and to owe its recurrence to similar conditions. But sometimes no cause whatever can be suggested either for the original outbreak or for the subsequent seizures.

*Symptoms and progress.*—The first attack comes on for the most part without warning, and at a time when the patient is otherwise in good health; and after lasting for a short time subsides suddenly, and leaves him apparently well. Subsequent attacks of variable duration, but re-

<sup>1</sup> ‘British Med. Journal,’ vol. i. 1867.

sembling the first in all characteristic features, come on at irregular and often long intervals, and the disease may thus be continued for many years without obvious injury to the patient's general health. Occasionally, no doubt, the attacks of palpitation diminish gradually in length and frequency, and the patient ultimately recovers; but perhaps more frequently they tend to recur at shorter and shorter intervals, and to last for longer and longer periods of time, and at length to induce the ordinary symptoms of obstructive cardiac disease or of cardiac debility.

The attacks of palpitation vary in length from a few minutes to several weeks. We have known them to continue without intermission for two or three months. The heart beats with extraordinary rapidity, its pulsations amounting to 180, 200, 220, 240, or even 300 in the minute. Its action is generally regular, but in some cases shows a tendency to intermission or to slight irregularity. The præcordial pulsation is diffused, the cardiac sounds short and sharp, and usually free from murmur. The pulse is small and weak, and difficult or impossible to count at the wrist. The condition of the patient varies: sometimes the face is a little dusky, and the expression distressful; sometimes there is slight dyspnœa; and generally a sense of fluttering or tremor in the chest, which is especially troublesome to the patient when he is in bed, and renders it difficult or impossible for him to lie on the left side. He is apt to be irritable and fidgety, and sometimes complains of a constant feeling of being in a hurry. The most remarkable thing, however, is not that the patient suffers from such symptoms as have been enumerated, but that, notwithstanding the persistent violent beating of his heart, for the most part his sufferings are slight: he is able to walk about freely, to perform his accustomed duties, and sometimes even to undergo severe and prolonged labour as though nothing were the matter with him. The feelings of distress often are most marked at the onset of an attack, and tend to subside during its course. The attack may come on at any time of the day or night, and for the most part comes on unexpectedly. Its termination is generally as sudden as its beginning, the action of the heart dropping in a moment from express speed to the rate of health. This sudden change is generally attended with a kind of throb or some peculiar sensation in the cardiac region, and sometimes by fainting or collapse. Now and then the pulse drops more gradually, or by a series of falls extending over some hours.

When the attacks of palpitation are much prolonged, or follow one another at short intervals, symptoms of impeded circulation are apt to supervene, such as anasarca, dilatation and pulsation of the larger veins, œdema, congestion and apoplexy of the lungs, with cough, hæmoptysis, dyspnœa, congestion of liver, and albuminuria. Cardiac murmurs may also be developed.

Although recurrent palpitation is essentially a functional disorder, it occasionally appears as a complication of organic heart-disease.

Cases are also met with which are probably of essentially the same kind as those to which the foregoing description applies, in which the

cardiac palpitation is characterised not only by great rapidity, but even more by extreme irregularity, of pulsation. In these cases the beats of the heart per minute may be not more than 140 or 150 ; this total number being made up, however, of alternate brief periods of comparatively slow pulsation, and of pulsation at the rate of 3, 4 or even 5 beats in the second.

*Pathology.*—There is very little post-mortem evidence of the nature of the disease. Sir T. Watson mentions a case in which an autopsy was made, and the heart was found soft, thin, and dilated, but otherwise sound. There is good reason indeed to believe that in typical cases this organ is structurally healthy. In one of our own, in which sudden death occurred, the heart was generally somewhat hypertrophied and dilated, but the muscular tissue and the valves were healthy. The disease is probably one affecting the innervation of the heart.

*Treatment.*—On this topic there is also little to be said. Digitalis alone or combined with iron has been found useful in some cases, but in others it has failed absolutely. We believe that a course of arsenic is sometimes beneficial. It is important that during an attack the patient should be kept quiet and free from excitement ; and that, when signs of impeded circulation show themselves, he should be treated as persons suffering from similar symptoms due to organic disease would be treated.

---

## X. CARDIAC NEURALGIA. ANGINA PECTORIS.

*Causation.*—The causes which induce cardiac neuralgia are numerous, but for the most part such as affect the circulation either through the nervous system or by muscular exertion. Among them are mental excitement, such as anger, or any sudden impression of pain or pleasure ; intemperance in eating or drinking ; active exercise, especially ascending a hill or staircase, and straining at stool ; in some cases even a blast of cold air. The attacks are often brought on by mere walking exercise, and not unfrequently occur during sleep. Cardiac neuralgia is of frequent occurrence in heart-disease and cases of aortic aneurysm, and under these conditions may be met with at any age and in either sex.

*Pathology, symptoms, and progress.*—Neuralgia of the heart is referred primarily and mainly to the præcordial region, and occurs therefore chiefly to the left of the sternum, but sometimes involves the sternal and right mammary regions as well. It varies in severity ; is aching, burning, or indescribable ; but is generally attended with a sense of constriction, dread of breathing deeply, and anxiety. It may radiate down into the lower part of the abdomen, up into the root of the neck, or backwards to the spine ; but is specially characterised by a tendency to extend to the left shoulder, and thence downwards along the inner side of the upper arm to the elbow. Not unfrequently it spreads to both shoulders, thence to both elbows, and thence again to the wrists and even to the tips of the fingers. Occasionally it involves the lower extremities similarly. The abnormal sensation which extends along the arms and lower limbs is sometimes an

aching, sometimes a sense of tightness or constriction, sometimes a tingling, and not unfrequently a mere numbness. In connection with these symptoms, the affected limbs, as also the face, suddenly become pale and cold; to which conditions venous congestion and clammy sweats are apt presently to succeed. During the height of the attack the patient often becomes giddy and faint, and sometimes falls into a state of insensibility which may be attended with convulsions.

Attacks of cardiac neuralgia vary in intensity, duration, and frequency of recurrence, and in the conditions under which they occur. They may be so slight as to consist in nothing more than a momentary pain or uneasiness in the region of the heart, with some extension to one or both shoulders. They may be so severe that the patient suffers, and has the appearance of suffering, indescribable agony, with the overpowering dread of impending death. He suddenly becomes still, fearing even to breathe; clutches whatever is near him for support; or, assuming some strange attitude which experience has taught him, grovels on all fours, lies upon his chest, or sits astride a chair with his face to the back, and his head bent over it. The attacks may last from a few seconds to many hours. In the latter case, however, their continuance is due to the repetition of paroxysms which are for the most part of no great intensity. Sometimes a patient has one attack only; or he has a succession of attacks at intervals, and then no more; sometimes the first is fatal; more commonly the affection commences comparatively slightly, with attacks succeeding one another at long intervals, but gradually the intervals become shorter, and the attacks more severe, and recur on slighter and slighter provocation.

When cardiac neuralgia occurs independently of distinct cardiac lesion it has received the name of *angina pectoris*. This is rarely met with below the age of forty or fifty, and is far more common in men than in women. In the majority of cases, too, it has a marked tendency to recur at gradually shortening intervals and with increasing severity, and sooner or later to prove fatal. Occasionally, however, the disease manifests itself in young persons; and occasionally also (and more particularly in them) complete recovery takes place eventually. After death from *angina pectoris*, various lesions have been detected; and these (the more important of which are calcification of the coronary vessels, and fatty and other degenerative affections of the muscular tissue of the heart) have been regarded as its cause. In other cases the heart has been found to be perfectly healthy. But it is obvious that such lesions as are here adverted to can only act, if they act at all, as predisposing causes. What, then, is the proximate cause? It has been assumed to be spasm or cramp of the muscular tissue of the heart; and in favour of this view it may be observed how intense is the agony which may be produced by the spasmodic action of the bowels, uterus, or voluntary muscles. The character of the pulse has been described as being sometimes weak and scarcely perceptible; at other times, slow, full, and strong. There is reason, however, to believe, both from the pallor and coldness of surface which attend the onset of the

attack, and from sphygmographic observation, that an essential feature of the disease is sudden and extreme contraction of the systemic arteries, which both prevents the free passage of blood to the capillaries, and, damming it up, as it were, in the heart, excites that organ to unwonted but more or less fruitless efforts.

*Treatment.*—The treatment of cardiac neuralgia, or angina pectoris, must be partly prophylactic, partly directed to the relief of the spasmodic attacks. It is of the greatest importance that the patient should avoid or obviate all those conditions which are apt to produce the affection; that he should eschew all mental and bodily exertion or fatigue; and that indigestion and all other functional derangements should be as far as possible prevented by careful attention to diet and appropriate remedial measures. For the treatment of the anginal attack various remedies have been suggested. Amongst the most valuable are the diffusible stimulants—ammonia, ether, and brandy—and narcotics, such as opium, and belladonna, and the inhalation of chloroform. During an attack, diffusible stimulants are probably the most useful. Faradism to the cardiac region has been attended with good results. Dr. Brunton, guided by the fact of the spasmodic contraction of the arteries which attends, if it do not cause, angina, has tried the inhalation of nitrite of amyl (which relaxes the muscular walls of these vessels) during the paroxysms with striking benefit. He applies five or six drops to the nostrils on a rag or piece of blotting paper. This method has since been largely employed, and with marked success. Nitro-glycerine (gr.  $\frac{1}{100}$ ), given in the form of pill, acts much in the same way as the nitrite of amyl.

---

## XI. CYANOSIS AND MALFORMATIONS

### A. *Cyanosis*:

*Causation.*—Lividity or blueness of the skin is a frequent symptom of those diseases or conditions in which the due aëration of the blood is interfered with, and especially, therefore, of some forms of lung and heart disease. It may be met with, consequently, in all cases in which impediment exists to the passage of air along the larynx or trachea; in all cases also in which there is obstructive disease of the bronchial tubes, whether it be bronchitis or any other affection; and in all cases in which, whether from emphysema or other organic lesions, or from pulmonary congestion or œdema, the free transmission of blood along the pulmonary capillaries, or the free admission of air into the air-cells, is interfered with. It is a striking characteristic of cholera; in which disease, either from alteration in the blood or from contraction of the smaller branches of the pulmonary artery, the blood ceases to pass in quantity through the pulmonary capillaries. Lastly, it is frequently observed in cases of heart-disease, more especially of the right side, and in cases of congenital malformation.

*Symptoms and progress.*—It is in the last class of cases, indeed, that the condition commonly known as cyanosis is most frequently present—

cases in which the blueness first manifests itself at birth, or within a few weeks, a few months, or very rarely a few years, after that event. We shall describe it as it presents itself in these cases. The blueness of surface varies in depth, but is always most pronounced in the cheeks, lips, tongue, and extremities of the fingers and toes. Here the natural rosy hue may merely present the slightest possible inclination to purple, or the parts may be purple, blue, or almost black. The general surface is dusky, or livid, and ghastly. The tint varies from time to time; it gets intensified under the influence of exertion, mental excitement, exposure to cold, or catarrhal or other like affections of the respiratory organs; and in some cases almost entirely subsides during times of comparatively good health, and perfect quiescence. The conjunctivæ are mostly congested, œdematous, and glistening; the lips, and perhaps the nose and eyelids, are tumid; but the most remarkable degree of tumefaction is always manifested by the terminal phalanges of the fingers and toes, which become strikingly thickened and enlarged, or bulbous. The circulation is feeble, the surface (especially that of the extremities) generally cold, and the patient disinclined, and indeed unable, to engage in active exercise. He is liable to paroxysmal attacks of difficulty of breathing, during which his cyanosis increases, and he not unfrequently passes into a state of syncope; and he is apt to suffer from congestive and inflammatory affections of the respiratory organs. He is generally sluggish in body and mind, and his temper is for the most part irritable and fretful. Dr. Peacock says that the internal temperature of cyanotic patients is not below that of healthy persons.

*Pathology.*—It is not unnatural to assume that the cyanosis of malformation is due to the admixture of arterial and venous blood, which takes place in the great majority of these cases, through an incomplete ventricular septum, a patent foramen ovale, or a persistent ductus arteriosus. But cyanosis has been proved to exist in an intense form in cases of malformation where no such admixture was possible, and to be absent from many cases of malformation in which the communication between the venous and arterial sides of the heart was unusually free. We are hence driven to the conclusion that cyanosis must in the main be due to the same causes that determine lividity in other forms of heart-disease, namely, impeded transmission of blood through the lungs, and consequently insufficient aëration, with over-accumulation of blood in the systemic veins. If this be the true explanation, it may fairly be asked what are the distinctive marks by which typical cyanosis is distinguishable from ordinary cardiac lividity? And it must be acknowledged that the differences are of degree or detail only, and are probably due to the fact that the veins of young children yield more readily under the continued strain to which they are exposed than do those of adults. Cardiac lividity in adults rarely attains that depth of colour which we often meet with in cyanotic children; and the bulbous enlargement of the fingers and toes which is so common in the latter case is seldom observed as a consequence of acquired heart-disease.

### B. *Malformations*

*Causation and morbid anatomy.*—The subject of cardiac malformations is one of great interest and extent, and impossible of adequate discussion in a work like the present. Yet it cannot be wholly ignored. We proceed, therefore, to make a few remarks upon it.

The auricles form originally a single cavity, and the separation between them is effected by the development of a vertical septum, of which the fossa ovalis represents the last-formed portion. This septum may be wholly absent; or the fossa ovalis may remain patent as it is at birth; and between these extremes every degree of defect may be observed. The ventricles also constitute, in the first instance, one cavity, which, in the course of development, becomes divided into two by the growth of a partition from the apex of the organ upwards, the last-formed part therefore being that which lies just below the arterial orifices. This septum also may be wholly or in part absent. In the latter event, the deficiency is almost always found immediately below the valves. The bulbus arteriosus, again, in the first stage of its development, is a single cavity continuous with that of the common ventricle, and becomes like that, by the growth of an independent septum, divided into two portions, of which one becomes the aorta, the other the pulmonary artery. It is possible for this separation never to be completed; it is possible that one of the arteries may be imperfectly developed or get impervious; it is possible also for them to be transposed, so that the pulmonary artery becomes continuous with the left ventricle, the aorta with the right. Further, the ductus arteriosus, which is patent up to the time of birth, may remain patent. Various valvular defects, for the most part causing obstruction, are also of frequent occurrence. Lastly, many of these malformations may co-exist, and indeed the appearance of one defect in the course of development usually necessitates the supervention of others at a later period, or the permanence of certain of the provisional arrangements of fœtal life.

Defect of either the ventricular or the auricular septum to a slight extent does not necessarily allow of any material admixture of venous and arterial blood, or involve discomfort or danger of life; if, however, the communication be free, the aerated and non-aerated blood-streams become more or less considerably commingled, and serious symptoms may result. It is obvious that similar consequences will ensue under various other circumstances; as, for example, when the tricuspid orifice is contracted or obliterated, and all the blood that enters the right auricle has consequently to pass through the foramen ovale into the left auricle and thence into the left or it may be common ventricle, previous to its distribution; or when, owing to relative displacement of an imperfect septum ventriculorum and of the orifices of the pulmonary artery and aorta, both vessels seem to spring from the right ventricle; or, when, assuming also the septum of the ventricles to be incomplete, the aorta or the pulmonary artery is contracted or impervious, and in one case the pulmonic circulation is effected from the aorta through the medium of the ductus arteriosus, in the other

the systemic circulation is maintained through the channel afforded by the trunk of the pulmonary artery and the ductus arteriosus between the heart and the descending arch of the aorta.

*Symptoms and progress.*—In the various forms of malformation which have here been passed in review, there is very often disproportion in point of size between the ventricles, and hypertrophy of their muscular parietes; consequently there is generally during life some extension of præcordial dulness, some modification of its form, and some increase in the area and force of the cardiac pulsations. Further, there is, in a large number of cases, a loud and rough systolic murmur, audible with greatest distinctness over the left third costal cartilage or somewhere between this point and the left nipple, and, according to its degree of intensity, perceptible over a restricted area only, or over the whole præcordial region and beyond it.

The general symptoms which attend malformations of the heart are (if certain valves only be affected) those mainly of obstructive disease of those valves; if, however, in addition to valvular obstruction, there be other congenital defects, or if, independently of valvular lesions, these other defects are sufficiently serious to cause symptoms, the patient presents in a more or less aggravated form the phenomena which have been described under the head of cyanosis.

The prospects of life in children born with malformed heart are very gloomy. The great majority die in the first few weeks after birth. A small proportion of them survive to the period of puberty. Few, however, who are markedly cyanotic attain adult life. The chief causes of death, according to Dr. Peacock, are: cerebral disturbance resulting from defective aëration of the blood and congestion of the brain; and imperfect expansion, collapse, and engorgement of the lungs.

### C. Treatment

The treatment of cases of malformation should be merely hygienic and prophylactic. Patients should be protected by warm clothing against vicissitudes of temperature, debarred from all active bodily exercise and mental excitement, and sustained by nourishing diet. Their digestive organs and emunctories should be maintained as far as possible in a healthy condition.

---

## SECTION II.—DISEASES OF THE ARTERIES

### I. ARTERITIS

#### A. *Periarteritis*

*Causation and morbid anatomy.*—The outer tunic of the arteries, and to some extent the middle and even the internal tunic, may be regarded as merely modified portions of the general connective tissue. They are directly continuous with it, and, as might be supposed, readily share in its

diseases. Hence, when a district of the body is in a state of inflammation, the walls of the arteries which are comprised within it also become inflamed; and occasionally, indeed, inflammation may attack these more violently than other parts, and may travel along them far beyond the limits of the primarily affected region. Such inflammation is usually limited to the outer tunic, and involves the others (if at all) comparatively late and to a slight degree. It is characterised by congestion, infiltration, and thickening of the affected parts; is sometimes attended with the development of pus in and around the outer arterial coat; and occasionally with ulcerative destruction or necrosis of the middle and inner coats, and consequent perforation. From the very slight extent in which usually the internal coat is implicated, it but rarely happens that the lining membrane loses its polish, or that thrombosis takes place.

The *symptoms* to which this form of arteritis gives rise are pain and tenderness, hardness and induration, along the affected vessel, and some degree of inflammatory fever. The formation of abscesses, the plugging of the artery, and its perforation would severally produce special symptoms. These, however, are matters which will be more conveniently discussed hereafter.

### B. *Endoarteritis*

*Causation and morbid anatomy.*—But, besides that form of inflammation which commences from without, we not unfrequently meet with inflammation which originates in the lining membrane, and tends to remain limited to that membrane, or at least involves the outer coats later and by simple extension only.

The causes of primary endoarteritis are somewhat obscure. It is due in some cases to the irritation of a thrombus or impacted embolus; in some to the effect of long-sustained excessive blood-pressure (as in Bright's disease), or to the continued violence of the impact of the blood-stream on certain points. It may be due to cold. It appears, too, in many cases to depend on cachectic conditions of the system, referrible to long-continued exposure, deficiency of food, intemperance, syphilis, and the like. Indeed, it may be asserted that syphilitic disease of arteries is, at least in many cases, scarcely if at all distinguishable from endoarteritis.

Endoarteritis of the larger vessels is indicated by the development in the substance of the internal coat of translucent wheal-like thickenings which project into the vascular channel. They have rounded or irregular margins, and often coalesce so as to form patches of considerable extent, which then present nodulated surfaces. They may be scattered singly in small numbers or may involve extensive tracts, rendering the surface of the vessels remarkably uneven; and they are particularly apt to appear at the points of bifurcation of vessels, or at the points of junction of branches with the trunks from which they spring. When the affection is the consequence of thrombosis, and when it occurs in minute arteries, it often causes uniform thickening of considerable superficial extent. The thickening is due to inflammatory proliferation of the protoplasmic elements

of the internal arterial tunic ; and it may be observed that, according to Cornil and Ranvier, the acute form of the disease is distinguishable from the chronic by the fact that in it the proliferation begins at the surface, which is consequently roughened, while in the latter it takes place chiefly in the substance of the tunic. After a while, the muscular coat becomes involved, degenerates and loses its contractile power ; and when the inflammation implicates the whole thickness of the vessel the walls become generally thick and translucent.

Syphilitic endoarteritis, more especially as it occurs in the cerebral arteries, has been closely studied by Heubner, who shows : that it begins with proliferation of the endothelium ; that gradually a growth forms which encroaches on the channel of the vessel, and consists of stellate and flattened cells ; that the innermost of these are in close contact and arranged as an endothelium, while the outer ones are more loosely aggregated, and separated from one another by some amorphous matter, and a greater or less number of leucocytes ; that after a time capillary vessels, continuous with those of the external arterial tunic, are developed in the growth ; and that it ends in cicatricial contraction, and does not, like ordinary endoarteritis, undergo fatty change. The morbid process is limited to certain arteries, and affects them irregularly. Dr. Greenfield<sup>1</sup> shows that the disease may attack the external as well as the internal coat, and that it may spread thence to the middle tunic.

*Symptoms.*—Endoarteritis may, as has been hinted, be acute or chronic, but there are no special symptoms by which its acuteness or chronicity can be distinguished ; and, indeed, endoarteritis becomes chiefly important and distinguishable by the consequences, mainly mechanical, to which it leads. These (which will be elsewhere more fully considered) are referrible to irregularity, rigidity, degeneration and weakening of the arterial walls, diminution or occlusion of the channel, dilatation or aneurysm, ulceration, and rupture ; to which may be added the consequences of the deposition of fibrine upon the roughened surface, and of the formation of granulations or pendulous fibrinous polypi. When endoarteritis occurs in superficial arteries, in consequence of thrombosis or embolism, considerable, sometimes extreme, pain and tenderness are experienced in the course of the affected vessel. It follows, therefore, that pain may be a symptom of the endoarteritis of deep-seated vessels.

The disease is sometimes slowly progressive. In one case under our care, in which no other signs of ill-health were present, it began in the arteries of the index and middle fingers, and in the course of several months gradually crept upwards until apparently all the arteries of the forearm and the brachial in its whole length were obstructed. Then the progress of the disease became arrested ; collateral circulation was established ; and gangrene which had been slowly taking place remained limited to the tips of the fingers.

<sup>1</sup> 'Path. Trans.' vol. xxviii. p. 249.

## II. DEGENERATION OF ARTERIES

*Causation and morbid anatomy.*—Primary fatty degeneration of arteries frequently comes on with the advance of years. It is recognised by the presence of irregular opaque yellowish spots, apparently in the substance of the internal membrane, which may be sparsely scattered or so abundant as to produce a general mottling. But, although it commences in the internal coat, it soon involves the middle coat as well. Microscopically it is found that the cells of the affected regions are the seat of more or less abundant fatty deposit. They gradually become entirely destroyed; and with the progress of the disease the intervening tissues, including the elastic elements and muscular fibres, disintegrate.

But more frequently fatty degeneration constitutes a late stage of endoarteritis. The translucent or cartilage-like nodules become opaque, generally in their interior, owing to the fatty transformation of the cells of which they are in so great a degree composed. And after a while the interior of the growth may break down into an opaque pulp, containing abundant fatty molecules, degenerate remnants of tissue and cholesterine. A small abscess-like cavity is the result. Or, as in the primary affection, the fatty degeneration may commence superficially and hence gradually invade the whole of the diseased patch.

Whether the degeneration be primary, or secondary to arteritis, there is a tendency after a while for the degenerated structures to break down and be discharged into the vascular channel. When the disintegration begins superficially, the affected surface gets eroded, and an ulcer-like cavity results. When, on the other hand, the softening mass is at first separated from the blood-stream by a layer of coherent tissue, perforation after a while takes place, and the escape of the detritus through the orifice results in the formation in the substance of the arterial walls of a flask-like cavity, which maintains a free communication with the arterial channel.

But fatty degeneration is not the only degenerative change which occurs. In a large number of cases, more especially chronic cases or those of persons advanced in years, precipitation of calcareous matter accompanies the fatty process. Calcareous molecules are deposited in the tissues which intervene between the fattily degenerating cells; and the result may be the formation either of amorphous tuberculated calcareous lumps, or more frequently of thin, transparent plates, which are curved in conformity with the curvature of the vessel, and which, though usually covered in the first instance by a thin membranous lamella, soon get denuded. Further, they tend to separate at the margins, and after a time to be shed wholly or in part, and to leave ulcer-like excavations behind. Calcareous plates may be scattered irregularly and in small numbers, or may be so numerous and large as to render the vessel in which they occur a rigid bone-like cylinder.

There is yet another form of calcareous degeneration which is occasionally met with in arteries of medium and small size. It is not attended

with, or consecutive to, fatty degeneration, but is due to calcareous transformation of the muscular cells of the middle coat. The capillary arteries occasionally undergo complete conversion into calcareous cylinders.

The degenerative processes above described, although for the most part originating in, and implicating mainly, the internal coat, tend sooner or later to involve the middle coat also; and, even if this present no visible structural change, it becomes after a time more or less impaired as to contractile power and capability of resistance. With certain exceptions which have been specified, degeneration affects the aorta (especially its arch) far more frequently than other vessels. Yet none enjoys immunity. The pulmonary artery, however, is comparatively rarely affected.

*Symptoms.*—The presence of arterial degeneration cannot always be recognised with certainty. It causes rigidity, and therefore loss both of elasticity and of contractile power. If superficial vessels be implicated, their condition may often be readily recognised by the finger; if the larger and deep-seated trunks be involved, the loss of their elasticity renders the systolic throb of the pulse prolonged and its cessation sudden; and, further, this same loss of elasticity adds to the resistance which the heart has to overcome, and tends to induce hypertrophy of that organ. The more serious and striking consequences of arterial degeneration are the same that have already been adverted to in connection with arteritis, and will be best discussed under subsequent headings.

---

### III. ANEURYSM (*Dilatation of Arteries*)

*Definition.*—The terms dilatation and aneurysm are of common use as applied to diseased arteries. By dilatation we generally mean a uniform or somewhat uneven enlargement of the channel of some considerable length of vessel; by aneurysm, a comparatively abrupt enlargement of a more or less distinctly circumscribed tract. The term aneurysm is, however, also applied to certain tumours which consist of bundles or convolutions of simply dilated arteries.

*Causation.*—Aneurysms, in the more restricted sense of the word, are bulgings caused by the pressure of the blood within vessels on walls which have been weakened either by the effects of accidental or other injury, or by the progress of the degenerative changes which have just been considered. The pressure which the blood within the arteries ordinarily exercises on their walls is amply sufficient to cause bulging and aneurysm at points in which their resisting power is impaired. It need scarcely be added that when that pressure is greatly increased, as it is habitually in Bright's disease, and intermittently in violent muscular efforts, its effect on diseased arteries is necessarily proportionately augmented; and, indeed, under some such conditions, tracts of even healthy arteries may undergo considerable and permanent dilatation. The influence of violence in the production of aneurysm is very important, whether we regard it as acting through the medium of the blood-pressure, or directly on the vessels by

strain. Its importance is shown: by the frequency with which aneurysms occur in those vessels which from their situation are especially exposed to violence; by the frequency with which they occur in those persons whose avocations demand excessive muscular exertion; and by the frequency also with which the origin of aneurysms may be distinctly traced back to some unwonted effort or injury. The starting-point of the aneurysm is then some laceration, probably of the middle coat, or, if the artery be already diseased, some injury to the degenerated tissue. But in the great majority of cases the aneurysm commences in a region already diseased, and probably independently of any undue pressure: the passive and enfeebled wall slowly yielding before the normal dilating force to which it is subjected. The surface left by the erosion of an atheromatous patch or the detachment of a calcareous plate, or the cavity produced by the discharge of a quantity of atheromatous detritus through a minute orifice, are all of them frequent sites of commencing aneurysm. But mere atheromatous change alone, apart from actual removal of tissue, especially if the middle coat be involved, will cause sufficient enfeeblement to allow of aneurysmal expansion. Other like causes of aneurysm are: especially in the cerebral arteries, the damage to their parietes effected from within by the impaction of emboli; and, notably in the case of tubercular vomicae, injury to arteries from without by the suppurative or necrotic changes going on in the tissues wherein they are imbedded.

Aneurysm is a far more common affection in males than in females, mainly on account of their different avocations; and it belongs almost exclusively to adult life. It is a disease, indeed, chiefly of advanced years; still it not unfrequently occurs, both in men and in women, between the ages of 30 and 40, and especially in those who have led debauched or hard lives, and have suffered from the conditions which produce endoarteritis.

*Morbid anatomy.*—Many needless refinements have been made in respect of the classification of aneurysms. We shall not waste time upon this subject, but will describe them with reference (1) to their form and size; (2) to the constitution of their walls; and (3) to the nature of their contents.

1. Aneurysms in some cases are mere globose or fusiform dilatations of some limited length of artery in its whole circumference. Much more frequently they are thimble-shaped or flask-like bulgings (then termed sacculated aneurysms), which involve the vessel in a portion only of its periphery. In the latter case the orifices by which they communicate with the artery vary greatly in size relatively to the aneurysmal tumours; are round or oval, with the long diameter corresponding to the axis of the vessel; and present tumid margins, which in large aneurysms, involving nearly the whole width of an artery, are distinctly developed above and below only. In other cases aneurysms present great irregularity of form. This may be due to the fact, either that several aneurysmal bulgings have taken place within a short distance of one another, and have coalesced during their progressive enlargement; or that the walls of the primary

aneurysmal sac have yielded unequally; or that they have ruptured or been destroyed at certain points, and the blood has escaped into fresh cavities by laceration, which form diverticula from the original aneurysm, and remain henceforth portions of it. The configuration of aneurysms is also greatly determined by the nature, arrangement, and resisting power of the structures which surround them and oppose their extension. The size which aneurysms attain depends in some degree on that of the arteries from which they spring. Aneurysms of the cerebral arteries are rarely larger than a walnut, whilst those of the aorta may vary from the size of a pea to that of a coco-nut or a child's head.

2. Occasionally the walls of an aneurysm comprise all the arterial tunics in a fairly healthy condition, as may be seen in fusiform or globose aneurysms due to general dilatation of a certain length of artery. In most cases, however, the condition of things is different:—The lining membrane of the artery may be traced, often somewhat thickened and pulpy, over the lips of the aneurysmal orifice, and thence with more or less distinctness over the whole inner surface of the aneurysm. The external coat also of the artery may be traced from without over the whole extent of the aneurysmal tumour. And as regards the middle coat, while in small aneurysms this may often be recognised as a more or less attenuated layer throughout their whole periphery, in larger ones it is usually incomplete, either stopping short around the orifice, or extending for a short distance into the walls, with traces of it still to be detected here and there throughout the rest of the circumference. Even when an aneurysm commences with perforation of the internal membrane of the artery, an adventitious lining forms before long, and becomes continuous with that of the artery. And indeed it is obvious that in all large aneurysms the laminae, which correspond to the inner and outer arterial tunics and are continuous with them, are mainly, if not entirely, of new formation. Further, these two coats become, in the course of time, identical in structure, and blend, enclosing within them any remnants there may still be of the middle coat. Not unfrequently also they become the seat of fatty or calcareous change. As an aneurysm extends, surrounding organs and tissues get involved in it, and take a share in the formation of its walls, the proper coats at the same time disappearing to a greater or less extent.

3. An aneurysmal cavity sometimes remains perfectly free from clot; sometimes, on the other hand, becomes in a greater or lesser degree obliterated by its slow deposition. The local conditions which favour coagulation are roughness of surface and comparative stagnation of blood. Both are usually present in perfection in aneurysms which originate in circumscribed bulging of an artery, and in which the orifice of communication is comparatively small. In these the process begins with the deposition of a thin adherent film upon the surface of the lining membrane. To this other films are added in slow succession; and hence the resulting mass of coagulum gradually assumes a laminated or stratified character. This process may, in fortunate cases, go on until the cavity is

obliterated, the last-formed laminae forming a kind of irregular bar or septum across its mouth. But more frequently the aneurysm is obliterated in part only, the coagulum being often limited to some diverticulum. When the lining membrane is fairly uniform and smooth, and the orifice large in relation to the cavity, there is often no attempt whatever at coagulation. And fusiform aneurysms, or aneurysms due to general dilatation, always remain free, or at all events never present more than such patches of clot as may be met with in an undilated aorta, of which the surface is studded with patches of atheroma or calcareous plates.

The origin of aneurysms in blood-pressure, which the arterial walls are incompetent to resist effectually, has already been considered. Their progressive enlargement is dependent on the continued operation of the same cause. In accordance with a well-known hydrostatic law, the force which the blood exerts on a given aneurysmal area is exactly equal to that which it exerts on an equal area of the artery in its neighbourhood; or, in other words, the total pressure on the inner surface of an aneurysm is in exact proportion to the superficial extent of that surface, and has no relation whatever either to the size of the orifice or to the form of the aneurysm. Consequently, the larger an aneurysm grows, the less capable its walls become of successfully opposing the blood-pressure within, unless they undergo some kind of compensative increase of strength. This, however, does not necessarily or even commonly occur.

The *effects of aneurysms* on the organs in their vicinity are in the main those of pressure, and necessarily therefore vary in importance and kind according to the situation in which the aneurysm is developed. When it occurs among easily displaceable organs it may attain considerable size without causing any special mischief or uneasiness. In all cases, however, surrounding parts sooner or later get pressed upon; if they are rigid they are gradually destroyed; if yielding they first yield, and only at a comparatively late period are involved in the aneurysmal parietes, and undergo the same fate as that to which the unyielding tissues more readily succumb. Thus bones and cartilages are gradually eroded; and their eroded surfaces, first exposed in the walls of the aneurysm, presently stand out from them into the interior of the cavity. Muscular and other soft tissues are first displaced, then flattened and compressed or stretched, and finally incorporated in the advancing wall and lost. Nerves and veins are similarly affected: pressure on the former causing pain, spasm, or other functional disturbance, and then paralysis or anæsthesia; pressure on veins producing impediment to the circulation, with subsequent congestion and dropsy. Similar effects of pressure may be exerted on the trachea, cesophagus, and intestines, and even on the brain, lungs, liver, and other solid organs, and in each case with the production of special symptoms, which we need not stop to discuss.

The *results of aneurysms*, unless a cure be effected by surgical procedure, are almost without exception unfavourable. In a small proportion of cases a cure takes place by the spontaneous filling up of the cavity with

laminated clot ; but generally the tumour continues to enlarge, and after a time causes death, by implicating some important organ, or by perforation and consequent profuse discharge of blood. The latter event may take place into one of the serous cavities, in which case the actual opening is usually caused by laceration ; or at the cutaneous surface or into one of the mucous canals, when perforation is due either to ulceration or to the separation of an eschar. Rupture or perforation may also take place into the cerebral or spinal cavities, the veins and even the heart itself.

*Symptoms and progress.*—The symptoms by which an aneurysm may be recognised are : first, those which are due to it as a simple tumour ; and second, those which depend on its relations with other parts. An aneurysm is usually a pulsating tumour. If it be empty of clot its pulsation is expansile like that of the arteries, and if it can be grasped the fingers which enclose it will be sensibly separated at each expansion. If it be full of clot no such expansion occurs ; and should pulsation be then felt it is merely such as may be presented by any other solid tumour lying upon an artery—the aneurysm simply follows the movements of the subjacent vessel. It is important to know that the mere imparted pulsation of a rounded tumour may easily be mistaken for expansile pulsation unless the tumour be grasped at its widest part ; for, if it be grasped in some narrower and more superficial zone, the alternate rise and retreat of the skin-covered wedge-like body between the fingers produce exactly the same periodical and measured separation of them which is so characteristic of true pulsation. The comparative hardness, however, of such a mass, and the probable fact that it may admit of removal from the influence of the subjacent artery, will generally correct any erroneous impression. The pulsation of an aneurysm is sometimes vibratile, especially if it be situated in the neighbourhood of the heart and associated with regurgitant aortic valve disease. It may be vibratile, however, owing to peculiarities of form and the condition of its walls and orifice.

Aneurysms are often attended with a murmur. This generally corresponds to the cardiac systole, and therefore to the tidal wave of the pulse, and is of a blowing character. It is probably created as a rule in the artery, and due either to contraction of its tube at the point of origin of the aneurysm, or to some irregularity at that part ; but it may be more or less modified, or in some cases developed, by resonance in the aneurysmal cavity. Murmurs may equally be produced by the pressure of tumours or even of the stethoscope upon healthy arteries. Aneurysms of the aortic arch, like other aneurysms, are sometimes attended with a murmur synchronous with the heart's systole, and like them may be free from murmur. But here a true double murmur is not unfrequent, especially if there be associated regurgitant aortic valve disease. In these aneurysms, again, it is not uncommon to hear the two cardiac sounds, or two sounds resembling them, even more distinctly than over the heart itself. They have been supposed to originate within the aneurysm, but

are doubtless the normal cardiac sounds carried by the blood-stream, and perhaps increased by resonance.

The pulse is often distinctly affected in aneurysm. But its affection is due not so much to the aneurysm itself (though this doubtless has some influence) as to the narrowing of the artery, from pressure or disease, which is so often associated with aneurysm. It is most obvious when the aneurysm involves either the innominate artery, the subclavian, the descending aorta, or one of the iliacs. In such cases the pulse in the implicated limb, as compared with that in the healthy limbs, is diminished in volume and strength, and appears to be retarded. The systolic rise is slow in attaining its maximum, and the diastolic fall presents a corresponding character.

The symptoms due to the direct influence of aneurysms on surrounding organs vary in different cases; but their general characters may be gathered from the remarks above made.

*Treatment.*—The treatment of internal aneurysms is far from satisfactory in its results. The chief object at which to aim is the gradual coagulation of blood within the cavity, and its consequent obliteration. This event occasionally takes place spontaneously in bed-ridden patients or those who are prostrated by lingering diseases—under conditions, therefore, in which the action of the heart and the circulation are unusually feeble. These facts furnish a clue to the general treatment which should be adopted. The patient should be kept at as perfect rest as it is possible to enforce. He should be exposed to no causes of mental excitement, and strictly debarred from all forms of muscular exertion, including that of straining at stool; if possible, therefore, he should be confined to bed. His diet should be light and nutritious, and not more abundant than is necessary to maintain him in a condition of fair, but not robust, health. Mr. Tufnell, whose treatment appears to have been attended with much success, restricts the patient's food to two ounces of bread and butter, and two ounces of new milk for breakfast and tea; and two or three ounces each of bread and meat with from two to four ounces of milk or claret for dinner. It is important, too, that the bowels should be kept moderately free by enemata or mild laxatives, and at all events not be permitted to get constipated; and that all bodily ailments which arise to complicate the aneurysm should if possible be obviated or cured. Various drugs have been recommended, with the object either of quieting the circulation or of promoting coagulation. Among those which have been employed with reputed success are acetate of lead, ergot, and digitalis, and of late years especially iodide of potassium in large doses. It may well be doubted, however, whether any one of these can have any real influence for good, and whether indeed digitalis is not likely to be injurious. Reduction of the volume of the blood, and of strength, by repeated copious venesections, was formerly largely advocated; and it is not improbable that, at any rate in some cases, occasional bleedings may be really beneficial. To relieve pain or uneasiness opium is invaluable, and as local applications, with the same object, ice, belladonna, and other

sedatives. The above remarks apply mainly to sacculated aneurysms. In fusiform aneurysms the deposition of laminated coagula is neither to be expected nor desirable; and meagre diet consequently is not only uncalled for but likely to be injurious.

#### A. Thoracic Aneurysms

*Morbid anatomy and symptoms.*—These occur principally in the different parts of the aortic arch, the descending thoracic aorta, and the roots of the large arteries arising from the arch. They spring most frequently from the ascending arch, and more commonly from the convexity than from the concavity of the arch. They usually form pulsating tumours which may be recognised as such if they abut on the surface of the chest, especially if also they be large, but which frequently escape recognition in consequence of being small or deep-seated. But whether they be recognised locally or not, they generally sooner or later induce characteristic phenomena by compressing the surrounding organs, and interfering with the due performance of their functions; and end fatally in one of several fully recognised modes. It is obvious that the situation of the tumour and the facility with which it may be recognised, the parts which are specially liable to compression, and the nature of the event, must be largely determined by the part of the aorta whence the aneurysm springs.

Aneurysms of that part of the aorta which is embraced by the pericardium are almost always of small size, and therefore liable to be confounded with simple aortic valvular disease, or degenerative arterial changes (with both of which they are commonly associated), or else altogether to escape recognition. They occasionally open into the pulmonary artery, right ventricle or auricle, or superior vena cava; sometimes lead to the production of loculated aneurysmal cavities, extending into the substance of the cardiac walls or along the auriculo-ventricular grooves; and are apt to rupture at an early period into the pericardial cavity.

Aneurysms of the rest of the ascending arch often attain a very large size. In their growth they encroach, as a rule, on the upper part of the right side of the thorax, displacing the lung outwards, and coming in contact by their anterior surface with the anterior thoracic parietes. Sometimes they involve both sides of the chest. They not unfrequently also displace the heart downwards and to the left. According to the amount of displacement of the lung or lungs will be the extent of the dulness on percussion to which they give rise, and that of their visible pulsation. This may be heaving, vibratile, or purring, and if visible to the eye will probably be seen to correspond distinctly with that of the heart. As the tumour enlarges it causes bulging of the chest-wall over it; and soon (eroding the ribs and their cartilages, the sternum, and perhaps the clavicle, and at the same time involving the muscular tissue) forms a more or less hemispherical pulsating mass. In the interior of

the chest it presses upon the right lung, which often becomes adherent to it and expanded in some degree over it ; and it is apt to compress the vena cava descendens or the right or left innominate vein, or all of them—impeding the passage of blood through them, or rendering them completely impermeable ; and it may even involve the right pneumogastric nerve or the sympathetic trunk. Aneurysms in this situation are liable to open externally, into the pericardium or right pleura, or into the lung itself and thence into one of the bronchial tubes, or even into the right bronchus.

An aneurysm of the transverse arch, if it spring from its front or convexity, expands chiefly upwards and to the left, so that it presses upon and erodes the manubrium of the sternum and the adjoining portions of the left upper ribs and cartilages, and clavicle, and forms a tumour which occupies the situation here specified, and tends to rise from behind the sternum into the root of the neck. If it spring from the concavity or posterior aspect of the arch, it is often quite latent. If it grow mainly upwards and in front, forming a manifest pulsating tumour, it may, like aneurysm of the ascending arch, attain a large size and eventually burst externally ; but much more frequently, owing to the confined limits of this portion of the chest and the many important organs which are contained therein, it causes death at a comparatively early period from the effects of pressure on one or other of those organs. Aneurysms of the transverse arch are especially liable to compress the trachea or left bronchus, and may also involve the œsophagus ; and often prove fatal by opening into one or other of these tubes. They may also compress or destroy the left recurrent laryngeal nerve, or the left sympathetic or pneumogastric trunk ; or obstruct the left innominate vein. Further, they may rupture into the pericardium, left pleura, or lung.

Aneurysms of the descending arch or of the rest of the thoracic aorta are rarely to be detected until they have acquired considerable magnitude. They become superficial by the destruction of the ribs and vertebræ in the dorsal region to the left of the spine, and there in some cases form pulsating tumours of enormous size. But before they cause manifest tumour they may sometimes be recognised by the presence of dulness, pulsation, and murmur, and the absence of respiration over a limited area. An important hint as to their presence is often furnished by the occurrence of more or less constant gnawing, aching, or burning pain in the situation of certain of the vertebræ, and of shooting or aching pains or uneasy sensations in the course of some of the nerves of the brachial plexus or of some of the intercostal nerves, more particularly on the left side. Aneurysms developed in these portions of the aorta not only tend to cause destruction of the bodies of the vertebræ and posterior parts of the corresponding left ribs, and to involve the dorsal spinal nerves and the sympathetic trunk of the same side, but are especially apt to compress the œsophagus and ultimately to open into it, or to rupture into the left pleura. They may indeed rupture into the right pleura, and even into the vertebral canal. Those arising in the upper part of the chest may also compress

the trachea, left bronchus or lung, and eventually open into one or other of them.

It may be convenient to pass in review the various pressure-symptoms to which aneurysms of the thoracic aorta give rise, and of which several are often present, when as yet no tumour can be discovered by auscultation, percussion, palpitation, or inspection. They are as follows:—

1. *Impediment to the arterial circulation.*—This may depend either directly on the aneurysm or on the presence of atheromatous or other thickening of the vessels springing from the arch. Not unfrequently the artery of one arm alone suffers, and the radial pulse of that arm becomes comparatively feeble, or it may be entirely annulled; sometimes both carotid and subclavian of one side are thus affected; and occasionally all the arteries springing from the arch are implicated, so that all visible pulsation in them and their branches ceases. When, however, the impediment to the circulation is thus general, it has usually come on gradually, and there have been previous stages in which one or two arteries only have been involved. In consequence of impediment to the carotid circulation, we not uncommonly find patients with aneurysm of the arch liable to momentary attacks of vertigo, or loss of consciousness, sometimes attended with epileptiform convulsions.

2. *Impediment to the venous circulation.*—When the vena cava or both innominate veins are obstructed, the veins at the root of the neck form spongy masses immediately above the clavicles, and those of the head, neck, arms, and upper part of the chest undergo great distension. The cutaneous surface gets congested, especially that of the face, the eyeballs injected and prominent, and before long the head, neck, and upper extremities swollen with œdema. The patient suffers also from drowsiness, coma, and other cerebral symptoms, and extreme dyspnœa. When one innominate vein only is obstructed, the venous distension and œdema are limited to one arm and one side of the head, neck, and chest. In this case, if the patient's life be prolonged, it is not unusual for remarkable clubbing of the fingers of the affected limb to supervene.

It is an interesting and important fact that even in cases of total obliteration of the descending cava, the resulting congestion and œdema of the head and neck and arms is not unfrequently to some extent averted or remedied by the establishment of vicarious venous routes. Occasionally we have seen the gradual development of a large vein descending from the neck over the clavicle, and entering at the first intercostal space to empty itself into the cardiac end of the vena cava; and in one case the return of blood to the heart was effected through a network of veins occupying the right shoulder and neighbouring part of the thoracic parietes, which emptied themselves into a huge tortuous vein that descended vertically beneath the integuments from the axilla to the groin to join the external iliac.

3. *Pressure on nerves.*—Pressure on the left recurrent laryngeal nerve is soon attended with paralysis of the intrinsic muscles of the larynx which it supplies. The left vocal cord becomes motionless midway between the position of closure and that which it should assume during ordinary calm

respiration, and the voice loses its musical character and becomes hoarse or whispering. Pressure on the right recurrent, which may be produced by innominate or subclavian, and exceptionally even by aortic aneurysm, has a corresponding effect on the right vocal cord. It has often been observed that in intrathoracic aneurysm one of the pupils (as compared with its fellow) is either abnormally dilated or, which is more common, abnormally contracted. Abnormal dilatation has been attributed to pressure upon the sympathetic trunk in the upper part of the chest, causing irritation; abnormal contraction to pressure on the same trunk, but sufficient to destroy it or annul its functions. The pneumogastric nerve is at least as liable as the sympathetic to suffer, and to its compression congestion and gangrene of the lungs have been attributed. The effects of pressure on the intercostal nerves and brachial plexus have already been considered. It may be added that pain is apt to shoot up the corresponding side of the neck. It is obvious that the phenomena of nervous interference must be looked for chiefly in aneurysms situated to the left of the mesial line; but they occur also in aneurysms of the ascending arch, and of course in those of the larger branches.

4. *Pressure on trachea and bronchial tubes.*—The constantly increasing pressure of an aneurysm on the trachea, if exerted laterally, displaces it to a greater or less extent; but under any circumstances the pressure sooner or later drives that portion of the surface against which it is exerted inwards, first flattening it, and then causing it to bulge so as to reduce the tracheal channel at this part to a mere semilunar chink. This process is attended with the gradual involvement of the tracheal walls in those of the aneurysm, and their infiltration with inflammatory products, followed by their gradual disintegration and final perforation. While it is going on, the patient suffers from stridor of the breath-sounds; which becomes especially audible when from excitement, exertion, or the act of coughing, the respiratory acts are hurried or deepened, and is attended with more or less dyspnoea. Gradually these symptoms increase, and cough is superadded. The cough is at first occasional and dry, but soon gets paroxysmal, and each paroxysm is relieved by the discharge of a small quantity of mucus. The stridulous respiration, and the stridulous cough in prolonged paroxysms (threatening and sometimes ending in suffocation), are peculiarly suggestive of the presence of an aneurysm or other tumour in the thorax. The suffocative cough is due to the occasional closure by mucus of the narrow tracheal chink, and the mechanical difficulty there then is in effecting its dislodgment. Hoarseness or loss of the musical quality of the voice only exists when, associated with the tracheal pressure, there is involvement of the recurrent laryngeal nerve, or some distinct affection of the vocal cords or their muscles. Accumulation of mucus in the bronchial tubes, lobular pneumonia, congestion of lungs, and pneumonia, are all of them common sequelæ of tracheal obstruction. When only one of the bronchi is obstructed, feebleness of respiratory murmur and imperfect expansion may be observed on the affected side of the chest, on which presently supervene rhonchus, crepitation, and other

signs of one or other of the lung-affections just enumerated. Further, in this case the aneurysm may also obstruct the pulmonary vessels going to and from the lung, and thus interfere with its nutrition. And from these combined causes may result consolidation of the lung, with breaking down of parts of it, and pleurisy with effusion.

5. *Pressure on the œsophagus* causes the ordinary phenomena of œsophageal stricture.

Thoracic aneurysms are often exceedingly difficult of diagnosis, partly because the symptoms to which they give rise are obscure, partly because many affections simulate them in their general and local indications. Among such affections may be included: persistent violent palpitation of the heart, such as is met with in Graves's disease; and hypertrophy and dilatation of the heart, associated with regurgitant aortic valve disease. In both of these conditions there is often violent pulsation, attended with purring tremor of the arch of the aorta and large vessels, and in both, marked præcordial pulsation; and the cardiac sounds may be propagated over a considerable portion of the right infraclavicular and mammary regions. There may even be, in the latter case especially, some retraction of the anterior edge of the right lung and consequent extension of aortic dulness to the right. Other conditions liable to be mistaken for aneurysms (especially if they be associated with palpitation or heart disease) are mediastinal tumours, consolidated portions of lung, and abscesses or growths involving the thoracic parietes.

In the foregoing account we have referred mainly to typical aortic aneurysms. But aneurysms of the intrathoracic portions of the large arteries which spring from the arch present much the same local and general symptoms as do aneurysms arising from the aorta itself in their immediate neighbourhood. They are to be distinguished mainly by their position and the special influence which they exert on the circulation through the arteries with which they are connected.

So-called *dissecting aneurysms* are not unfrequent in the aortic arch. They are produced by the sudden laceration of the diseased or merely thinned internal coat of the artery, and the effusion of blood through the rent into the interval between the external and internal coats, and generally into the substance of the middle coat. The extent to which the dissection may take place, and the event, both vary. In some cases, the dissection is limited to a small well-defined area; in other cases, it circumscribes the vessel, and occupies an inch or two of its length; and in other cases, again, it involves the whole extent of the aorta. As regards result, dissecting aneurysms occasionally undergo spontaneous cure by the coagulation of the extravasated blood; sometimes they prove fatal by causing complete obstruction of the aorta, in the thorax or abdomen; but more frequently they terminate in laceration of the external membrane, and the effusion of blood into some cavity, such as the pericardium, or into the connective tissue of the mediastinum or some other part.

*Treatment.*—In addition to the general plan of treatment which has been laid down for aneurysms, it is sometimes possible, from the fact that

aneurysms of the ascending and transverse arch and of the vessels which spring from them come speedily into relation with the anterior walls of the chest, to employ mechanical or other means to cause coagulation within them. The methods which have been had recourse to, but unfortunately with very imperfect success, are the injection of perchloride of iron or other styptics, the insertion of coils of thin iron wire, horsehair, or needles, and galvano-puncture. For the last purpose a battery of from ten to thirty cells should be employed, the plates being preferably of small size. The needles connected with the poles should be as large as medium-sized harelip pins, and sheathed in vulcanite to within a short distance of their points. They should be plunged vertically into the tumour, and retained there for twenty or thirty minutes, or until some effect has been produced on its condition. The operation should, if necessary, be repeated at intervals of a few days. Ligature of the subclavian and carotid arteries, especially those of the right side in aneurysm of the ascending arch, has occasionally proved beneficial; it is less useful, however, here than in the treatment of aneurysms of the roots of these vessels.

#### B. *Abdominal Aneurysms*

*Morbid anatomy and symptoms.*—Aneurysms may be developed in connection with any part of the abdominal aorta or of its branches within the abdomen. Those which chiefly concern the physician are connected with the aorta, cœliac axis, superior and inferior mesenterics, renals and common iliacs. The sources of abdominal aneurysms must be determined by their anatomical relations. They may generally, while still of medium size, be recognised as distinct pulsatile tumours, attended with more or less thrill and often with a murmur. It is easy, however, in thin persons, to mistake the pulsation of the abdominal aorta for that of an aneurysm, and especially so to mistake a carcinomatous or other tumour situated upon the aorta. Indeed, it is often impossible to distinguish accurately between an aneurysm and such a solid mass, unless by grasping the tumour we can distinctly satisfy ourselves that it does not expand, or by displacing it from its contiguity with the aorta we annul its pulsations. Abdominal aneurysms generally tend to attain a large size, to cause erosion of the vertebræ or other bones with which they come in contact, and to press upon the stomach, duodenum, or other viscera, veins, or nerves. They then cause: pain in the back, which is sometimes very agonising, and often shoots along the branches of the lumbar nerves; sickness from pressure on the stomach or obstruction of the duodenum; compression and even obliteration of the inferior cava, or one of the common iliac or renal veins, with dilatation of the veins of the lower extremities, and anasarca; or similar conditions in one lower limb only, or in a kidney. Abdominal aneurysms occasionally burst into the peritoneal cavity, or into one of the hollow viscera, or even into the spinal canal. More frequently they rupture primarily into the retro-peritoneal tissue; whence blood may be effused round the duodenum, or œsophageal opening of the stomach, or into the

substance of the mesentery, mesocolon, or great omentum, and may thus before the supervention of death cause complete obstruction of the cardiac orifice, duodenum, or some other part of the bowel, and sometimes the most intense and long-continued agony of pain.

*Treatment.*—The most important of the special modes of treatment of abdominal aneurysms are: first, that of putting a ligature round the aorta; and, second, that of regulated pressure upon the aorta. The latter method may be carried out by the temporary application (say for eight or ten hours), under the influence of chloroform, of a specially adapted tourniquet to the aorta, if possible on the proximal side of the aneurysm. Pressure may be applied, with almost equal efficacy, on the distal side. It must not be forgotten, however, that the application of sufficiently forcible pressure completely to obstruct the aorta is attended with great risk of serious injury to the abdominal viscera; and hence it will generally be best to delay its employment until the effects of perfect rest have been fully tested. Galvano-puncture may sometimes be employed here as in other cases.

---

### SECTION III.—DISEASES OF THE VEINS

#### I. PHLEBITIS\*

*Causation and morbid anatomy.*—Inflammation of a vein is generally due: either to the formation of a clot within it, in which case the process commences at the inner surface and travels outwards; or to the involvement of the vein in inflammatory processes which are going on round about it, in which case its walls are invaded from without inwards. Phlebitis, indeed, is almost always secondary. Exceptions to this rule are furnished by inflammation of the uterine veins after parturition, and by the comparatively rare thickening of the inner coat of veins which corresponds to the much more frequent thickening of the inner coat of arteries issuing in atheromatous and calcareous degeneration. The presence of clots may be regarded as an essential accompaniment of all forms of phlebitis, with the exception of the chronic form last adverted to.

Inflammation of veins is characterised by thickening of their walls, connected with proliferation of the protoplasmic elements of their several laminae. The latter process is generally especially active in the outer coat, which not unfrequently acquires considerable thickness and blends with the surrounding similarly affected connective tissue; and scattered abscesses are apt to appear here and there in its course. The inner coat tends to become rough, and even to give rise to granulations. The contained clot, whether it be formed primarily or secondarily, soon fills the channel of the vein and adheres more or less firmly to its inner surface. At the same time it tends to lengthen both above and below—above to the junction of the vein with the next branch or its communica-

tion with a trunk vein, below into the tributary branches. The further changes which such clots undergo will be considered under the head of thrombosis.

The *local symptoms* of venous inflammation are pain, and, if the vein be within reach of direct observation, tenderness in its course, with cylindrical thickening and hardening, and sometimes superficial redness. Abscesses in the course of the vessel, communicating or not with its interior, are not unfrequent. There is necessarily febrile disturbance; and this is sometimes excessive and bearing an exact resemblance to that of pyæmia, being marked by rigors, sweats, and rapid transitions of temperature from the normal or subnormal to an elevation of  $107^{\circ}$  or more. The remote effects of phlebitis are on the whole much more important than the local effects. They embrace: on the one hand, those due to venous obstruction—dilatation of the distal veins, congestion, and anasarca; on the other, besides fever, those dependent on the discharge of fragments of thrombus, or of inflammatory or other hurtful matters into the circulating blood. These will all be best considered hereafter.

---

## II. VARIX (*Dilatation of the Veins*)

*Causation.*—Dilatation of veins is much more common than that of arteries, but its causes are a good deal more obscure. It occurs, no doubt generally, in obstructive disease of the right side of the heart; and, when a vein is obstructed, throughout the venous system which is tributary to it, as well as in those collateral veins which take on, or divide between them, the duties of the defaulting vessel. But in a large number of cases veins get dilated and varicose independently of all obstruction, independently of overwork, and independently also of obvious degeneration or weakening of their walls.

*Morbid anatomy.*—When veins dilate they become at the same time elongated and consequently tortuous. The dilatation usually commences, and is always most marked, immediately above the valves; and the affected veins assume, therefore, an irregular moniliform aspect. The walls, for the most part, thicken considerably, although presenting occasional attenuations, especially over the convexities of the dilated portions. The thickening is principally due to hypertrophy of the middle coat, the attenuation to its atrophy or disappearance. With the progress of dilatation the valves become inefficient, and often shrivel up; calcareous plates not unfrequently form in the middle coat; the connective tissue around gets thickened and indurated, and blended with the outer coat of the vein; phlebolites are often developed in the pouch-like protrusions; and the last occasionally become perforated either by extension of ulceration from without or by laceration.

Dilatation may occur either in veins of medium or large size, or in those which are ordinarily mere capillary tubes. The former occurrence is exemplified by the ordinary varicose veins of the lower extremities, and

by varicocele, the latter by the tuft-like groups so common in the lower limbs of pregnant women. Dilatation and varicosity of veins rarely require treatment at the hands of the physician. For him they serve mainly as important aids to diagnosis. Varicose veins in the lower extremities, varicocele, and hemorrhoids are surgical disorders. Dilated or varicose veins of internal organs no doubt occur, and aid in the production of functional disturbance; they may even rupture and cause death by hemorrhage. We have witnessed this accident in the case of varicose veins of the œsophagus. But their presence can rarely if ever be recognised during life. The importance of the dilatation of certain groups of superficial veins in enabling us to judge of the seat and character of internal diseases involving the obstruction of deep-seated veins is obvious.

---

#### SECTION IV.—ARTERIAL AND VENOUS OBSTRUCTION

##### THROMBOSIS AND EMBOLISM

*Definition.*—There are few morbid processes of greater interest, and at the same time of greater practical importance to the physician, than those which we are now about to consider. They are the frequent causes of many obscure complaints, as well as of some of the most clearly characterised maladies; they may involve any organ of the body, and present at least as many different groups of symptoms as there are organs; and they are intimately related to some of the gravest forms of disease which come under our notice, such as pyæmia and puerperal fever. The term *thrombosis* has been conveniently applied to the coagulation of blood during life in the heart, arteries, or veins, and includes within its meaning nearly all those cases which were formerly regarded as phlebotic. The term *embolism* has been introduced to designate those cases in which an artery or vein gets plugged by the impaction in it of a clot or other solid mass conveyed to it from a distance by the blood-stream. The morbid phenomena and symptoms which thrombosis and embolism induce are referrible partly to local inflammation, but principally to arterial or venous obstruction.

##### A. *Thrombosis*

*Causation.*—The causes of thrombosis are mainly: stagnation or sluggish movement of the blood; the contact of the circulating fluid with inflamed or otherwise diseased surfaces; and special conditions of the blood which render it apt to coagulate.

*Morbid anatomy.*—1. In the *heart*, after death, the blood which was contained within its cavities at the moment of death is generally found coagulated, moulded to the form of the cavities, and continuous with cylindrical clots occupying the trunk veins, and often with similar clots extending into the trunk arteries. These clots are sometimes black-currant-jelly-like, sometimes partly decolorised; and the portions pro-

longed into the arteries are usually more or less purely fibrinous, while those seated in the veins are usually soft and black. But not unfrequently the clots contained in the heart's cavities, and more especially those occupying the ventricles, are almost entirely fibrinous, opaque, and buff-coloured, close in texture, and even indistinctly laminated. These have for many reasons obviously formed during life, probably during the agony; but are the consequence of dying and not the cause of death; and on the whole (except from the fact that their deposition helps, as it were, to confirm the fatal issue) have little clinical importance. Their presence, however, throws light on the development of the peculiar bodies next to be considered. It is not uncommon to find after death in certain cases that rounded, buff-coloured masses, varying perhaps from the size of a pea to that of a walnut, are situated either in the apical portions of the ventricles, or in the appendages of the auricles. These, which are sometimes termed softening clots, usually occur in groups, are moulded to the surface on which they lie, adhere to it, and are continuous with one another by processes which underlie the *carneæ columnæ*; so that, with careful dissection, they may generally be removed as a continuous whole. They are sometimes smooth, sometimes ribbed, upon the surface, and often variegated in colour. On section they may present a uniform character and consistence; but are more frequently broken down in their interior into a thick reddish or yellow pus-like fluid, containing products of disintegration only—namely, fat-granules, degenerating red and white corpuscles, cholesterine, and sometimes hæmatoidine crystals. The bodies are clots, in fact, which have formed in the heart's cavities sufficiently long before death to have undergone the degenerative changes which clots formed elsewhere also undergo. They may be found in any of the heart's cavities; in one alone, or in two or more at the same time; but are much more common in the left ventricle than elsewhere. The conditions under which they are found are various; but they are especially frequent in cases of advanced heart or renal disease in which the patient has lain for weeks with an extremely feeble circulation, and the balance trembling between life and death. During this period the enfeebled heart probably fails to empty its cavities completely; the blood remains stagnant or nearly so in those portions of them which are most remote from the direct current; and coagulation takes place either slowly, or more probably suddenly, on one of those occasions, which are so common in these cases, when the patient falls into a state of apparent death, from which he rallies. Other clots of old formation, which may be found in the heart, are laminated clots such as occur in aneurysms. They may be present in actual aneurysmal dilatations of the ventricles, and have been discovered behind a closely constricted mitral orifice almost entirely occluding the left auricle.

2. In the *systemic veins* the coagulation of blood during life is common enough. When the venous circulation is simply enfeebled, as in the later stages of heart-disease, and towards the close of phthisis, carcinoma, and other chronic wasting affections, venous thrombosis is of frequent occur-

rence. It then takes place more particularly in the trunk veins of the lower extremities, and in those of the pelvis or at its brim. So again when some impediment exists to the passage of blood along a vein, the distal portion of the vessel and, in a greater or less degree, its tributary branches fill with clot. When veins are involved in inflammation which is taking place round them, this, as has been pointed out, tends soon to pervade the entire thickness of the walls, and then to induce coagulation of the blood within them and their complete obstruction; and occasionally, indeed, by perforation of a vein or some other process, pus or other inflammatory products find their way into its interior, or into the substance of the thrombus. Thrombosis, secondary to inflammation, is common in erysipelas, diffuse cellular inflammation, carbuncle, and the like; in puerperal pelvic cellulitis; in inflammation involving the cancellous structure of bones, or the walls of the parturient uterus; and in the venous sinuses of the interior of the skull in connection with disease of the internal ear.

The different characters which venous thrombi display depend largely upon their age, and correspond with those presented by cardiac clots. When fresh either they have a uniform consistence and colour, or they present a central black cylinder, enclosed in a fibrinous capsule. They do not necessarily at once fill the vessels in which they are seated, even if they be adherent to them, and hence fresh blood tends to insinuate itself between them and the venous parietes, and presently to coagulate there. The clots which finally occlude vessels thus get more or less distinctly laminated. In their further progress venous thrombi undergo various changes. In some cases they blend with the venous walls, and, becoming converted into connective tissue, cause the obliteration of the vessels; in some they undergo softening in their interior, and conversion into loculated cavities full of fatty detritus and caseous remnants of white corpuscles; and occasionally they suppurate and form abscesses.

3. *Arterial thrombosis* is due in a large number of cases to simple stagnation of blood. Thus the arteries leading to a district, in which (owing to morbid processes going on in it) the blood has ceased to circulate, get filled secondarily with coagulum. And in precisely the same way, if an artery be ligatured, or obliterated at any point by the pressure of a tumour or tourniquet, the proximal portion of the vessel up to the nearest branch becomes the seat of thrombosis. Not unfrequently also, when the circulation is simply feeble, obliteration of an artery by coagulation of its contents takes place. This occurrence in the smaller branches of the pulmonary artery is a common cause of pulmonary apoplexy. It is occasionally also observed in the arteries of the extremities and even in the aorta itself. Diseases of the inner coat of arteries (atheroma, calcification, arteritis, and syphilis) are all of them liable to induce thrombosis and consequent obliteration. Among arteries especially liable to suffer thus are those of the base of the brain and of the extremities. The varieties of arterial clots and the changes which take place in them are identical with those already described in connection with veins.

B. *Embolism.*

*Causation and morbid anatomy.*—The sources of emboli are mainly venous thrombi, cardiac vegetations, and disintegrating calcareous, atheromatous, or inflamed surfaces. Additional sources are softening clots in the interior of the heart, and morbid growths or other adventitious bodies.

The detached solid mass, whatever its nature, is carried along by the blood-stream until it reaches a vessel which is too small to allow of its further progress. The point at which it becomes finally arrested usually corresponds to the bifurcation of a vessel or to the giving off of a comparatively large branch. Here it gets wedged, sometimes blocking up the channel completely, but more frequently forming at first a partial impediment only. In the latter case the constant pressure from behind tends to drive it farther and farther onwards, in consequence of which, or of the gradual coagulation of blood around it, the vessel becomes at length, as in the former case, completely occluded. Subsequently thrombosis takes place on both sides of the embolus; the artery and its distal branches get filled with clot which, gradually undergoing changes, blends on the one hand with the arterial parietes, and on the other with the embolus. So that although the embolus may, at first, be readily recognised as an independent body, it often becomes undistinguishable from the thrombus to which its presence has given rise.

Emboli taking their origin in the systemic venous system, or right side of the heart, necessarily become fixed in the pulmonary arteries. Those which originate in the pulmonary veins, left side of the heart, or larger systemic arteries, are conveyed to the periphery of the systemic arterial circulation. And those, lastly, which are yielded by the veins of the chylopoietic viscera find their resting-place in the branches of the vena portæ.

Owing to the infrequency of disease of the valves of the right side of the heart, embolism involving the lungs is almost invariably due to the detachment of venous clots or fragments of them. In some cases entire systems of thrombi become free, and a complete cast, some inches long, of a venous tree may be carried into the pulmonary artery and impacted in a convoluted form within it. More frequently shorter lengths get successively separated and successively lodged in different branches of that vessel. It is much more common, however, for venous clots to crumble as it were gradually away; and for minute fragments to get impacted from time to time in the pulmonic arterioles.

It is rare for thrombosis to take place in the pulmonary veins; and hence embolism is seldom due to this cause. The most common source of embolism of the systemic arteries is undoubtedly the detachment of granulations from the diseased aortic or mitral valve; but another frequent cause is the separation of atheromatous or calcareous particles, or other detritus, either from the valves or inner surface of the heart, or from the large arteries. It is obvious, therefore, that embolism of the systemic

arteries must in a very large proportion of cases depend on valvular disease, and is to be regarded as one of the common risks of that affection. Emboli from the various sources just indicated are carried along the aorta and thence into some of the smaller branches of the systemic arteries; whither is in some degree a matter of accident; but there are certain parts—namely, the brain, liver, spleen, and kidneys, and, it may be added, the lower extremities—which are specially prone to suffer. It is probable, however, that their arteries are not so much specially liable to obstruction, as that their obstruction produces particularly serious and obvious ill-effects. The cerebral arteries chiefly liable to occlusion are the middle cerebral branches of the internal carotids; and it is curious that the stoppage generally occurs in the middle cerebral of the left side.

### *C. Consequences and Symptoms of Thrombosis and Embolism*

Whenever a thrombus forms or an embolus becomes fixed, inflammation of the implicated vascular walls, if it did not previously exist, speedily ensues; and hence pain and tenderness soon mark the course of the vessel if it be within reach of investigation, and febrile disturbance generally arises. In either case complete obstruction to the passage of blood through the affected vessel takes place very soon if not quite suddenly. It is this fact, indeed, which gives to thrombosis and embolism in common their characteristic features, and which renders it difficult, if not impossible, to make any practical distinction between them. In aid, however, of correctness of diagnosis it may be pointed out: first, that obstruction of the pulmonary, hepatic, and systemic veins by clots can depend on thrombosis only; second, that obstruction of arteries or of the portal veins may be due either to thrombosis or to embolism; third, that the pre-existence of systemic venous thrombosis renders it probable that any obstruction occurring in the pulmonary arteries is due to embolism; and, lastly, that the presence of valvular disease on the left side of the heart, or the fact of previous rheumatism, is presumptive evidence that supervening obstructive disease of any of the smaller systemic arteries is of embolic origin.

The results of venous thrombosis are stagnation of blood in the tributary veins with dilatation, soon followed by œdema and compensatory enlargement, of the anastomotic veins. These conditions are not secondary to thrombosis only, but attend all cases in which veins, from whatever cause, are obstructed. The consequences of arterial thrombosis or embolism, on the other hand, are impairment of nutrition of the region which the artery supplies, and, following on this, congestion, hemorrhage, inflammation, degeneration, or gangrene, together with special symptoms due to the organ or part whose integrity is compromised. Similar phenomena necessarily ensue upon all forms of arterial obstruction, no matter how they are produced. The special effects of thrombosis and embolism will for the most part be best discussed in connection with the other morbid conditions of the several organs in which they occur. There are two or three cases, however, which may be most conveniently considered now. They are phlegmasia alba dolens, thrombosis and embolism of the heart and

pulmonary artery, obstruction of the larger arteries of the limbs, and multiple embolism of the smaller systemic arteries.

1. *Phlegmasia alba dolens*.—This term is generally applied to the painful and œdematous condition of leg which often follows upon parturition. An almost exactly similar condition may, however, occur independently of parturition, and even in males, and is not unfrequently developed in the course of phthisis and carcinoma. The arms also may be affected in like manner as the lower extremities. *Phlegmasia alba dolens* is due to thrombosis of the trunk veins of the limbs, or of the larger veins to which these converge, which become converted into painful rigid cords. When it follows parturition it generally begins from a week to a month after that event, and almost always in the left lower limb. And even if the right become affected it is usually affected in company with the left, but at a later period. The commencement of this disease is generally sudden, and indicated by the concurrence of diffused pain throughout the affected member, and œdema. The pain varies in character and intensity, and is generally attended with soreness or tenderness, sometimes with distinct hyperæsthesia, sometimes with loss of sensation; and not unfrequently the patient is unable, either from pain or from loss of power, to move the limb or any of its parts. The œdema gradually increases until the member gets large and smooth, and of a peculiar pale waxy aspect; it does not generally pit distinctly on pressure, and often presents remarkable elasticity and tension. The superficial veins usually become dilated and unnaturally visible; and the skin often presents a mottled, retiform character, owing to the rupture, as in pregnancy, of the deeper layers of the cutis. There is not, as a rule, any manifest change of temperature in the affected limb; but general febrile disturbance is usually present. If there be no serious complication, the patient probably recovers at the end of three or four weeks. For the most part, however, the veins primarily obstructed remain impervious; and sometimes there is permanence of œdema.

*Treatment*.—Little can be done in the way of special treatment for *phlegmasia dolens* or other œdematous conditions arising from obstructed veins. It is generally desirable that the patient be kept at rest, and the affected limb elevated or in the horizontal position. If there be distinct inflammatory mischief in the course of a large vein, a few leeches may be serviceable; and, when œdema and tenderness are present, it is generally of benefit to envelop the limb in wadding or flannel, in order to keep it warm and promote perspiration. Hot fomentations and baths may also be employed. The internal treatment must be determined by the general condition of the patient; but for the most part tonics are chiefly indicated.

2. *Cardiac thrombosis*.—It is not easy to specify symptoms by which clots formed in the heart during life may be recognised. It is possible of course that, from their position, they may occasionally interfere with the due action of the valves, and so induce endocardial murmurs; but it is certain that in the great majority of cases they have no such effect. It may be taken for granted that their presence must in almost all cases be

a source of embarrassment to the heart's action, and that they must therefore tend to aggravate the feebleness of circulation out of which they arose, and to increase the severity of the cardiac symptoms which the patient had previously suffered from. It is important, however, to note that when such clots form in the heart, the feebleness of circulation which determines their presence there very commonly also determines their formation in arteries and veins; and that hence the condition of the lungs and kidneys, connective tissue, and skin, may be of some assistance in the formation of a diagnosis. The detachment of such a clot and its entanglement in one of the valvular orifices of the heart have been assigned as a cause of sudden death.

3. *Embolism and thrombosis of the pulmonary artery.*—We do not intend here to discuss the results of that blocking up of the smaller branches of the artery which is so commonly associated with, and so often the cause of, pulmonary apoplexy, lobular pneumonia, circumscribed abscesses, patches of gangrene, and the like. Our object is to consider those embolic or thrombotic obstructions of the arterial trunk, or of its chief divisions, which are occasionally the cause of sudden death.

It is now well established that the chief danger of thrombosis of the larger systemic veins lies in the separation of the whole or a large portion of the clot, and its impaction in the trunk of the pulmonary artery. This accident is apt to occur in cases of phlegmasia dolens, and where, after parturition, the uterine veins have become plugged. The patient, probably in the midst of apparently fair health, is suddenly seized with severe pain in the region of the heart, attended with intense distress and gasping for breath, pallor or lividity of face, and extreme feebleness or even suppression of pulse, and dies collapsed. It has been disputed whether death is due to asphyxia or syncope. It is certain, however, that the sudden obstruction of the pulmonary artery causes shock, or collapse, and that the patient sometimes dies of this shock within a few seconds; and it is further certain that the symptoms of sudden obstruction are often undistinguishable from those of angina, or rupture of an aneurysm, or of the heart itself, into the pericardial cavity. Indeed, the symptoms of pulmonic obstruction are by no means typical; and its diagnosis must depend mainly on the association of the symptoms above described with those conditions of the venous circulation which are known to be productive of embolism.

There are two or three points, however, in relation to this subject which demand a word or two of comment:—First, sudden obstruction of the pulmonary artery by an embolus, even if attended with symptoms of great severity, does not necessarily end in immediate death. The clot may be driven onwards into a branch, the symptoms of impending death subside, and the phenomena due to the obstruction of a branch only presently ensue. Secondly, it is important to bear in mind that many of the recorded cases of sudden death from pulmonary embolism are cases in which the only foundations for this diagnosis were: suddenness of death, possibly from syncope; and the discovery after death of an ordinary

fibrinous clot in the right ventricle, prolonged thence into the pulmonary artery and its branches—a clot originating in the spot in which it was found, and the consequence of dying, not the cause of death. Thirdly, thrombi sometimes form in the larger branches of the pulmonary artery. Occasionally, indeed, the trunk and the greater number of its ramifications are almost entirely occluded by them. It is a fact that these may form without pain, and cause little or no distress, until by some little displacement of them, or by the sudden coagulation of the blood still circulating between them and the walls of the tubes in which they lie, they suddenly bring the pulmonary circulation, and with this life itself, to a stop.

4. *Embolism and thrombosis of the larger systemic arteries.*—It sometimes happens that, from either embolism or thrombosis, one or more of the arteries of the legs, the femorals, the iliacs, or the abdominal aorta itself, become obstructed. And the same thing may occur in respect of the arteries of the upper extremities. The immediate result is serious impediment to the circulation through the implicated limb or limbs, characterised by cessation, or at any rate diminution, of pulsation in the vessels beyond, and more or less pallor and coldness. In some cases collateral arteries gradually enlarge, and the general condition of the limb after a time becomes normal. In other cases, the circulation comes generally, or in certain areas, to a permanent standstill, the affected parts gradually lose their temperature, the surface gets pallid, but mottled with purplish spots, and the tissues assume a doughy consistence, bullæ, filled with sanious fluid, soon rise upon the discoloured patches, and dry gangrene becomes established. Arterial embolism is generally attended with severe pain at the point of impaction, and much pain and tenderness are generally present in the course of the plugged arteries. Usually, moreover, pain and tenderness are, for a time at least, present in a greater or less degree in the parts which are in process of sphacelation.

The causes of sudden aortic obstruction are usually either the establishment of a dissecting aneurysm, or the displacement of the laminated coagula formed in an aneurysmal pouch. In either case the patient is suddenly seized with severe pain, deep seated in the thorax or abdomen, and paraplegia. At the same time, pulsation disappears from the lower extremities, and their temperature falls. Of course under these circumstances gangrene and a fatal issue are to be anticipated. But in most cases, if the patient survive sufficiently long, circulation is re-established to some extent, and the gangrene becomes arrested in its progress. Occasionally no gangrene whatever ensues, and at any rate temporary convalescence takes place. The exact seat of aortic obstruction may be determined in some cases, either by the recognition of pulsation down to a particular point, or by the condition of the kidneys or bowels. If the renal arteries be obstructed, the urine is likely to be scanty, and to contain albumen or blood, or to be temporarily suppressed; if the mesenteric arteries, enteritic or dysenteric symptoms and tympanites may possibly ensue.

*Treatment.*—For the local treatment of gangrene little can be done beyond keeping the parts warm. To this end they may be greased and covered with cotton wool or wadding. For general treatment, it is chiefly important to maintain the patient's strength by the administration of food and stimulants, aided by tonics; and to relieve pain and distress by opiates.

5. *Multiple embolism of the smaller systemic arteries.*—This is usually the consequence of *ulcerative endocarditis*, or of the gradual erosion and disintegration of parts of the endocardium (mainly the aortic and mitral valves) which have been the seat of inflammatory thickening and overgrowth. It may come on in the course of acute rheumatism as a complication, or it may supervene accidentally, so to speak, in persons suffering from chronic heart-disease.

It depends on the constant or repeated discharge into the blood-stream of minute fragments of detritus, or emboli; which, distributed throughout the system, obstruct the smaller arteries, and mainly those of the kidneys, spleen, and liver—causing infarcts with attendant inflammation, which is apt to spread from the solid organs to the serous membranes. The exact nature of the embolic changes occurring under the above circumstances in different parts of the organism has been described in the article on pyæmia, and will be further considered in connection with the diseases of particular organs. There is little doubt that the ulcerative process itself and the general symptoms associated with it are referrible to the influence of septic organisms, which have been detected in the valvular ulcers, and other diseased tissues, and that the disease is closely related to pyæmia.

The symptoms of ulcerative endocarditis have a close resemblance to those of pyæmia, but on the whole are less intense, and less rapidly terminate in death. The patient generally has rigors, with elevation of temperature, up, it may be, to 105° or more, and perspirations. The febrile symptoms intermit, sometimes several times a day. The respirations increase in frequency; the pulse becomes rapid and feeble or irregular; the tongue gets coated; cough frequently supervenes with mucous and then sanguinolent expectoration and local indications of pulmonary congestion or consolidation; anorexia, thirst, nausea or sickness, and oftentimes diarrhœa ensue; the spleen generally enlarges and sometimes gets distinctly tender; occasionally jaundice supervenes; the urine frequently contains albumen and sometimes blood; the patient becomes restless, delirious, or drowsy, and sometimes at length comatose. In addition, inflammation of the joints or serous membranes, and roseolous, petechial, or pustular rashes are occasionally developed. The collective symptoms, nevertheless, are very often vague and misleading, and are liable to be mistaken, not only for those of pyæmia, but for those of tuberculosis, enteric fever, or ague. Most frequently, no doubt, the disease chiefly simulates chronic pyæmia; and, if its source in cardiac disease were overlooked, would be taken for pyæmia. Its resemblance to ague is occasionally very remarkable. In a case formerly under our care, which lasted altogether several months, the main symptoms were typical ague-

like paroxysms, often coming on twice in the twenty-four hours, and separated by intermissions of complete apyrexia, associated with gradual failure of strength, and drowsiness finally passing into coma. In one case death resulted from plugging of the left middle cerebral artery; in another from effusion of blood into the substance of the brain, probably following on an embolic aneurysm; in another from obstruction of both femorals by large emboli.

Slight attacks of this affection doubtless occur not unfrequently, are recovered from, and overlooked; but where it is present in an aggravated form it is probably always fatal sooner or later, often in the course of two or three weeks; sometimes, however, not for several months.

For *treatment* little can be done, beyond relieving symptoms, reducing fever, and maintaining the patient's strength.

---

## SECTION V.—DISEASES OF THE DUCTLESS GLANDS, BLOOD, ETC.

### I. GRAVES'S DISEASE (*Exophthalmic goitre*)

*Definition.*—An affection first described by Graves and Basedow, in which are associated palpitation, enlargement of the thyroid body, and exophthalmos or protrusion of the eyeballs.

*Causation.*—These associated phenomena are most commonly met with in young women above the age of puberty; they are seldom observed in girls of younger age, and seldom originate in advanced life. Men are affected much less frequently than women. The patients are, in some cases, anæmic or hysterical, but by no means invariably so. Sometimes the commencement of the disease dates from an attack of fever, or is attributed to mental shock or over-exertion. Occasionally it ensues on organic lesions of the heart. By some it has been contended that the cardiac disturbance precedes, and is the cause of, the goitre and exophthalmos. But against this view is the fact that long-continued palpitation is constantly met with in persons who never have any apparent tendency to affection of either the orbit or the thyroid body. Others have regarded the goitre as the primary lesion, and have referred the cardiac and other symptoms to its influence, exerted either by pressure on the arteries of the neck or in some less obvious manner. It is sufficient, however, in opposition to this view, to point out that Graves's disease is sometimes present without thyroid enlargement, and that palpitation and exophthalmos are not specially common among the goitrous inhabitants of goitrous districts. The proximate cause, indeed, of the disease is very obscure. Nevertheless there are many circumstances which render it probable that the collective symptoms are due to some affection of the sympathetic system, which allows of passive dilatation of the vessels of the neck, thyroid body and orbit, and at the same time of excited action of the heart. Many of the symptoms, in fact, closely accord with those producible either by paralysis or by functional disturbance of the sym-

pathetic. Moreover, various observers have described, in fatal cases of the disease, morbid conditions of the cervical sympathetic.

*Morbid anatomy, symptoms, and progress.*—The symptoms of Graves's disease may come on suddenly or gradually. In the latter case the patient probably first complains of violent and frequently repeated cardiac palpitation, together with distressing pulsation of the arteries in the neck. After these phenomena have existed for an indefinite period, changes are observed in the eyes and thyroid body. The affection of the eyes, if not actually prior in point of time to that of the thyroid body, is generally perceived earlier. At first the change is slight, and chiefly evident to those to whom the patient's healthy aspect is familiar. The eyes are a little more prominent, glistening, and staring than they were, and probably present the phenomenon (not, however, peculiar to this disease) to which Von Gräfe has called attention—namely, that in movements of them downwards the upper lids lag a little, allowing the whites to be seen for an instant above the corneæ. But gradually their prominence becomes more and more pronounced, until they protrude so far through the eyelids that these are unable to close in sleep, and even at ordinary times are so widely separated that the corneæ are visibly encircled by the sclerotics. Occasionally even the insertions of the recti muscles can be clearly distinguished. The exophthalmos is generally equal on both sides. Occasionally, however, it begins unilaterally, and, even when both eyes become involved, continues more pronounced on one side. It is curious that inflammation rarely attacks the insufficiently protected eyeballs; and that sight remains for the most part unaffected, excepting, perhaps, that the patient is troubled with *muscæ*, becomes long or short sighted, and suffers from fatigue in using the eyes. The protrusion of the eyeballs is often variable to some extent, increasing under the influence of palpitation, or excitement, and at the menstrual periods; and it appears to be due either to accumulation of fat, or of fat with increase of connective tissue, in the orbits, or to dilatation of the orbital vessels, or to these conditions combined in various proportions. It is often attended with aching or throbbing in the orbits, and not unfrequently subsides wholly after death.

The enlargement of the thyroid body is for the most part very gradual. It causes at first merely a slight fulness in the usual situation of the gland, but more especially on the right side, and is subject to variations in degree. Sooner or later, however, a manifest tumour results. This may be symmetrical, or may continue to be a little larger on the right than on the left side, but rarely attains a large size, or produces injurious effects by pressure on neighbouring parts. This form of goitre is more vascular and generally softer than ordinary goitre, and is often attended with a thrill and arterial murmur. The murmur and thrill, however, are rarely if ever developed in the tumour itself; but are due to compression of the common carotid, and are best marked where this artery resumes its normal calibre, namely at the upper margin of the tumour, and especially on the right side of the neck. Venous murmurs

also are not unfrequently developed in the neck and upper part of the chest of goitrous patients. The thyroid body in this disease is very liable to variations in size, and sometimes after a time shrinks to its normal dimensions.

The condition of the palpitating heart varies somewhat. For the most part its action is violent and rapid and apt to be irregular, and its sounds are loud and ringing; its area of dulness is often increased. In most cases it is at first structurally healthy, and so it may continue. Often, however, the persistence of palpitation induces hypertrophy and dilatation. Occasionally, as has been already intimated, the phenomena of Graves's disease supervene on actual cardiac disease; and in most cases in which post-mortem examinations have been made, atheromatous change has been detected in the arterial system.

The phenomena above described are not the only ones commonly presented in this affection. It has been especially observed that the patient is liable to be irritable, fretful, peevish, incapable of application, and to suffer from sleeplessness; that her hands are tremulous; that her appetite is capricious, often voracious; that she suffers from flatulence, and at one time from constipation, at another from diarrhœa; that there is a disposition to febrile excitement, with elevation of temperature by one or two degrees, and that this condition may be associated with the presence of Trousseau's 'cerebral macula'; that there is generally amenorrhœa, and not unfrequently leucorrhœa; that the complexion is liable after a time to become sallow or dead-leaf-like, and the hair to get dry, thin, and scanty. Anæmia and cachexia are also sometimes present. In some cases enlargement of the spleen has been observed; and in some, enlargement of the mammæ. It should not be forgotten that hysterical symptoms are apt to be associated with the symptoms special to Graves's disease. Dr. G. H. Savage<sup>1</sup> has drawn particular attention to the fact, which had previously been observed, that patients with exophthalmos sometimes become insane; and that their insanity is usually acute mania, and often proves fatal.

It should be added that, in the early stage, palpitation, with throbbing of the vessels in the neck, may be present without obvious thyroid-gland or eye affection, and that in some cases the goitre, in some the exophthalmos, never becomes developed.

Graves's disease is not usually dangerous to life. Occasionally patients recover entirely; more commonly there is partial amendment only; and in a large number of cases the disease is slowly progressive, and at best after a while becomes stationary. When death takes place it is mostly the consequence of some intercurrent affection, more especially of the lungs. Occasionally the enlarged thyroid gland compresses the trachea, and causes stridor and dyspnœa; and in rare cases, of which we have had one under our own care, causes death by asphyxia.

*Treatment.*—There is considerable difference of opinion as to the treatment of this disease. Some recommend, Trousseau condemns, the use of

<sup>1</sup> 'Guy's Hospital Reports,' vol. xxvi.

iodine. Iron is generally strongly advocated; both Trousseau and Von Gräfe, on the other hand, regard it as injurious. Depletory measures, and even the removal of blood, have been lauded. Digitalis in largish and frequent doses is said to promote contraction of the dilated and pulsatile vessels, and thus to relieve and cure the disease. It is probably of more real value than any other remedy. On the same principle ergot of rye or lead may be supposed to be indicated. Belladonna again seems to act beneficially. Cold applications to the thyroid body and to the præcordial region are said to be serviceable. If the patient be anæmic, or suffer from amenorrhœa, want of sleep, or any other condition calculated to cause or maintain ill-health, special treatment will of course be indicated. When the enlarged thyroid body causes dangerous symptoms from pressure on important parts, operative measures may be needed. Owing to the vascularity of this form of goitre, its resection is attended with great danger. But when the isthmus is small this may be divided with the same beneficial results that attend its division in ordinary goitre.

---

## II. DISEASES OF THE THYROID BODY

To diseases of this organ the term 'goitre' or 'bronchocele' is commonly applied. It is more convenient, however, to restrict these names to a certain group of hypertrophic affections than to include under them every variety of lesion to which the thyroid body is liable.

The chief affections which would on these grounds be excluded are inflammation and carcinoma.

*Idiopathic inflammation* of the thyroid body is certainly of unfrequent occurrence; it may, however, follow secondarily upon goitre, or result from operation, or injury inflicted upon the gland. It is probable also that some of the overgrowth of the hypertrophic organ may be due to chronic inflammation.

*Carcinoma* of the thyroid body is rare. It may be either primary or due to extension from neighbouring organs, or secondary, in the usual sense of that term.

It is needless to discuss particularly the symptoms to which these conditions give rise, or the special treatment they may require.

### A. Goitre (*Bronchocele*)

*Causation.*—The circumstances under which goitre arises are various and not very clearly understood. It is far more common in females than in males; and indeed, as regards women, it has long been known that there is not unfrequently a tendency to temporary enlargement of the thyroid body both during pregnancy and at the catamenial period. It is occasionally observed in the fœtus, and is then commonly associated with some peculiarity in the form and situation of the gland.

Goitre appears to originate mainly between the ages of eight and puberty; rarely, if ever, after forty. It occurs in a sporadic form in probably all parts of the globe; that is, isolated cases, for which no

cause can be assigned, are nearly everywhere occasionally met with. It is remarkable, on the other hand, that goitre is endemic in many limited areas scattered nearly all over the world. Such places are, in England, met with in Derbyshire, Hampshire, Nottinghamshire, Sussex, and Yorkshire. Goitrous districts are, as a rule, of peculiar geological formation: they are mostly valleys; and usually their soil, or that of the adjoining mountain ranges, is formed largely of lime or magnesian limestone; and the water of the wells or watercourses which traverse them is largely impregnated with carbonate or sulphate of lime, with which in a considerable number of cases magnesia is associated. Various reasons have been assigned for the prevalence of goitre in these localities. All evidence, however, seems to point to the drinking water as the efficient agent in its production; and it is generally held that the poisonous ingredient is either sulphate or carbonate of lime, or both, in combination probably with magnesia. The main objection to this view (and it is a serious one) is, that hard waters containing such ingredients in excess occur and are used in non-goitrous localities by persons who never become goitrous. And hence it is probable, as is suggested by Virchow, that these salts do not themselves act, but that associated with them there is some other principle of a malarious character to which the disease is really due. Endemic goitre is endemic in the strict sense of the term: it belongs, as it were, to the locality; new-comers are liable to suffer equally with those who have been born and bred in it (allowance being of course made for the relative length of their exposure to the goitrous influence); and, although the children of goitrous parents become in large proportion goitrous in such localities, the tendency is not hereditary, and ceases in them when they are removed from the influence of the poisonous principle. In goitrous districts the disease is not limited to man; but dogs, mules, and horses are liable to suffer.

*Morbid anatomy.*—Goitre consists in a kind of hypertrophy of the normal constituents of the gland—namely, the blood-vessels, connective tissue, and groups of intercommunicating vesicles forming the ultimate lobules which the connective tissue circumscribes. In some cases all of these become increased in equal proportion, and the goitre then differs little if at all, except in bulk, from the healthy organ. More frequently one of these constituents undergoes disproportionate development, and hence the texture of the tumour becomes characteristically modified. Thus, sometimes the connective tissue alone undergoes hypertrophy, and the tumour gets hard and dense; sometimes the vascular tissue especially becomes preternaturally developed—the veins and arteries, or more frequently the veins alone, attaining comparatively enormous dimensions; sometimes the vesicles are the chief seat of change—becoming dilated and filled with an albuminous fluid, or a solid albuminoid or gelatinous substance. Such cysts, partly by simple dilatation, partly by coalescence, may attain the size of a pigeon's or hen's egg, or even a larger bulk. In a case recorded by Mr. Spencer Watson, a cyst of this kind yielded on puncture a pint and a half of blood-coloured fluid. It must be added:

that cysts of considerable size may be developed in glands which are in all other respects healthy ; that a goitrous tumour may become, in whole or in part, the seat of inflammation, and that consequently blood may be poured out into the cysts which it contains, or suppuration and ulceration may take place in it ; and that degenerative changes may ensue after a time, the cells within the cysts undergoing fatty disintegration, and the contents of the cysts consequently acquiring a milky character, or the fibroid stroma becoming the seat of earthy deposition—a change often attended with diminution in size and induration of the tumour.

A bronchocele varies in consistence according to the nature of the processes which have been going on in it ; so that in some cases it is hard and resisting, in others it is soft and yielding or elastic, and in others, again, presents in certain situations distinct fluctuation ; and, when the enlargement of its arteries constitutes a special feature of the tumour, there may be pulsation resembling that of aneurysm.

A goitre sometimes retains accurately the form of the healthy gland ; but more frequently it becomes unsymmetrical in the progress of its growth (the right lobe being especially liable to disproportionate development), and then by growing in certain directions, or throwing out lobules, may press inconveniently or dangerously on important organs in its vicinity. Occasionally small supplemental thyroid bodies may be detected in the neighbourhood of organs thus hypertrophied ; and it is mainly by the development of such masses at the posterior part of the lateral lobes that compression of the œsophagus is sometimes effected.

The size of a goitrous tumour varies from that which produces a mere fulness (by some persons regarded as ornamental) in the lower part of the front of the neck, to a mass (usually irregular in form) as large as a cocoa-nut, or in rare cases of such enormous dimensions that it hangs pendulous from the neck, concealing the chest, the chest and abdomen, or even extending to the middle of the thighs.

*Symptoms and progress.*—A goitre may generally be readily recognised by its relations with the various structures occupying the lower and anterior part of the neck, and especially by its situation in front of the trachea, and by its following the movements of that tube. Its development is seldom attended with pain, and not usually with uneasiness ; nevertheless various injurious consequences are apt to ensue. In the first place the tumour may prove seriously inconvenient by its mere bulk and weight. In the second place, it may exert pressure on the large veins in its neighbourhood, or on the trunk of the sympathetic nerve, or on the pneumogastric or recurrent laryngeal, or on the brachial plexus. And in the third place it may displace and compress the œsophagus or trachea. Pressure on the œsophagus is induced mainly by enlargement of the posterior parts of the lateral lobes or of the supplemental bodies occasionally found in this situation. Pressure on the trachea is by far the most important of the consequences which goitre entails. In some instances it acts unilaterally, the trachea being displaced towards one side of the neck ; in some instances this tube is compressed between the two enlarged lateral lobes ; in some the pressure is exerted

in the antero-posterior direction, the trachea then becoming more or less flattened against the spine. The effect of pressure in either of these cases is often remarkable: the implicated portion of tube being sometimes flattened, sometimes made to form a convex bulging, so that consequently the passage becomes on transverse section semilunar or concavo-convex, or (if pressure be exerted equally on opposite sides) a rectilinear or biconcave chink, and sometimes actually obliterated. A slight amount of compression is not unfrequent, the patient breathing naturally when quiet, but with some degree of stridor and difficulty under exertion or excitement, and yet not with sufficiently pronounced difficulty to excite alarm in himself or others. In all such cases, however, there is danger of the supervention of fatal obstruction. In some this takes place gradually from the slow encroachment of the tumour; but in many it comes on more or less suddenly either from the rapid development of some cyst, or from inflammatory tumefaction, or from congestion and œdema of the mucous membrane of the already compressed trachea. The danger of suffocation depends less on the size of the goitre than on its form and situation; the most serious cases, indeed, are: first, those of *sub-sternal goitre*, in which the lower portion of the gland, or some process of it, sinks, in the course of its enlargement, behind the sternum, and compresses the trachea there, while there is yet little obvious sign of thyroid gland enlargement; and second, those of *sub-maxillary goitre* (a congenital defect described by Virchow, in which the gland is situated at a higher level than natural, and the lateral lobes extend backwards behind the angles of the jaws, and sometimes as far as the mastoid processes. The contraction of the sterno-thyroid muscles may materially aggravate the compression of deep-seated organs. To the list of dangers just enumerated may be added that due to the rupture of cysts or abscesses either externally or into the trachea or œsophagus.

*Treatment.*—In the treatment of goitre we have to consider: first, the medicinal and other means by which the tumour may be either reduced in size or prevented from increasing; and, second, the measures which may be requisite to obviate the effects of its pressure upon important parts. Whenever a goitrous patient lives in a goitrous district the obvious remedy is his removal to some more salubrious locality; or, if this be impossible, a careful investigation of the available drinking water of the neighbourhood, and the selection for use of that which is least contaminated with earthy salts, or the adoption of measures, such as boiling, distillation, or Clark's process, for the precipitation of these ingredients previous to use. Such measures, and especially emigration, are often efficacious in the complete removal of goitrous tumours which are of small size, or have been but a short time in existence, and are generally beneficial even in advanced cases. Burnt sponge was formerly largely employed, and with reputed benefit, in the treatment of goitre; but Dr. Coindet of Geneva, after the discovery of iodine in sea-water and marine productions, was led to suspect that the efficacy of the burnt sponge was due to the iodine which it contained, and to make trial of iodine itself as an anti-goitrous remedy. Since that time iodine and its various preparations have replaced almost all other internal

remedial agents, and have enjoyed a singular reputation as specifics against the disease. The testimony, indeed, in favour of the curative influence of iodine is almost overwhelming. On the other hand, it must be remarked : that, altogether apart from the influence of iodine, goitre is liable to considerable fluctuations of size, and when small and recent often disappears entirely ; that there is little or no evidence that the drug is efficacious in the treatment of exophthalmic goitre, which is structurally identical with the endemic form of the disease ; that, notwithstanding the supposed curative action of iodine, there is no proof that goitre is now less prevalent or less severe in goitrous localities than it formerly was ; and that mixed up with the evidence in favour of the specific virtues of iodine, is evidence equally striking in regard to the production of a remarkable concurrence of symptoms known by the name of iodism which now seems never to attend the use of iodine, however largely it is administered. We must confess that, in our own limited experience of the treatment of goitre, iodine has signally failed. But we need not limit ourselves to the employment of internal remedies. By many persons counter-irritants applied to the surface of the tumour are strongly advocated. Among such applications may be enumerated, iodine paint and other iodic preparations, strong mercurial ointment, and blisters or other forms of blistering agents. In some cases (generally, however, when the tumour has been of large size or has given indications of compressing vital organs) operative measures have been resorted to. The tumour has been excised—an operation of no inconsiderable difficulty and danger, owing to the relations of the thyroid body and its enormous vascular supply ; it has been treated by passing a seton through its substance and so exciting and maintaining inflammation or suppuration in it ; and, again, one or more of the arteries supplying it have been tied. Each of these operations has proved more or less successful in certain cases ; but none of them sufficiently successful on the whole to encourage its frequent performance. The recently introduced procedure of removing the isthmus of the enlarged gland, or of excising a wedge-shaped portion of the isthmus involving its whole thickness, promises to be of great value, and, in the cases to which it is applicable, of little risk. The isthmus itself, even in goitres of large size, often remains small ; and generally, as the result of the operation, the gland slowly shrinks, haphly to its normal bulk. Cysts of the thyroid body admit in most cases of ready and successful treatment, either by simple puncture with the discharge of their contents, or by puncture and injection of some stimulating fluid, or by the employment of the seton.

When goitrous tumours are threatening to obstruct the trachea, we must be alive to the possibility of the supervention at any moment of sudden and fatal asphyxia. What can be done under these circumstances ? If the enlargement be mainly cystic, relief no doubt can be afforded by the puncture of the cyst and the discharge of its contents. If, however, it be solid, as in the main it commonly is, the question of the performance of tracheotomy must naturally present itself, but tracheotomy in these cases is both difficult and unsatisfactory ; for it can rarely be performed

below the seat of obstruction; it is a formidable operation if effected through the substance of the enlarged gland; and, if done above the gland, it is necessarily useless unless it be completed by the passage of a sufficiently long tube through and beyond the constricted portion of the trachea.

### B. *Cretinism*

Cretins are persons in whom feebleness of intellect or idiocy is combined with certain peculiarities of bodily conformation. They are for the most part stunted in growth, with tumid bellies and coarse skins. In a large proportion of cases they are goitrous, though occasionally the goitre is of the latent or sub-maxillary kind, to which reference has already been made. The head is usually large and misshapen—expanded at the sides and flattened at the top; the cheek-bones high and prominent; the nose flattened or sunken at the bridge, broad at the root, and up-turned; the interval between the eyes increased; the lips thick; the mouth wide and open; and the tongue large. There is generally muscular weakness, deficiency of cutaneous sensibility, and impairment or annulment of the sexual functions; and not unfrequently deaf-mutism is conjoined with the other corporeal defects. The degree of mental impairment varies between complete dementia and mere dulness or slowness of intelligence. Cretins are usually quiet and harmless, not given to mischief, but liable to occasional outbursts of ungovernable violence.

True cretinism appears, according to Virchow's researches, to manifest itself during foetal life in an unnatural tendency which the basilar portion of the occipital bone, and the post-sphenoidal and præ-sphenoidal bones, have to coalesce with one another by ossification of the discs of cartilage by which they should at that time be separated. The consequences are: that the base of the skull prematurely ceases to elongate, and thus becomes modified in form; and that this arrest of development leads, on the one hand, to widespread changes in the osseous framework of the skull and face, and, on the other, possibly to defective development of the corresponding portion of the brain. The form of the skull gets modified, partly by the need which its contraction in one direction involves of compensatory expansion on the part of those regions whose bones have not yet coalesced, and partly by the opposing tendency which also exists in these cases to precocious union of the bones of the cranial vault along the lines of suture. The peculiar form which the face assumes is due in some measure to imperfect development of the nasal septum, in some measure to displacement of the cheek-bones and bones of the orbits. Further, in many of these cases the cranial bones acquire remarkable thickness, and the foramina at the base of the skull become much diminished in size. The same tendency which is presented by the cranial bones is presented by those of the extremities, which soon unite with their epiphyses. And, indeed, it is probably due, in part at least, to this cause that these bones remain incompletely developed.

According to the above account of the pathology of cretinism, this

condition must be regarded as of congenital origin. Children are born cretins; that is, they are born, either with the peculiar features of cretinism already obviously developed, or with that coalescence of the bones at the base of the skull which necessitates the gradual development of cretinism during the period of childhood.

Like goitre, cretinism may occur either sporadically or endemically. The causes of sporadic cretinism and those of sporadic goitre are alike obscure. Endemic cretinism, however, and endemic goitre are always associated, and obviously originate in a common cause. Wherever goitre prevails largely, there cretinism is also prevalent; the goitrous tendency, however, occupies a wider area, and goitrous persons always largely outnumber their idiotic compatriots. It would seem, indeed, that for the production of cretinism some special intensity of the poison which also causes goitre is requisite. Cretins are not only in large proportion goitrous, but also in large proportion the offspring of goitrous parents. Yet there is no sufficient reason to believe that cretinism, any more than goitre or ague, is hereditary; for goitrous parents do not beget cretinous children when once they have removed from the regions in which these affections prevail; and under similar circumstances the children of cretins are themselves free from both goitre and taint of cretinism. It seems clear, indeed, that the morbid matter which, taken into the mother's system, renders her goitrous, acts also on her fetus, causing in it, maybe, not only goitre, but also those special developmental changes which ultimately lead to malformation and mental deficiency. In reference to the association in cretinous infants of arrested development of the base of the skull and goitre, it is interesting to bear in mind the fact, pointed out by Virchow, of the close proximity in the fetus of the base of the skull to the thyroid body. Assuming the common cause of goitre and cretinism to be, or to have some close relation with, the existence of a superabundance of earthy salts in drinking water, it is natural to speculate on the influence which these salts may have in causing the too early completion of the process of ossification.

We have referred to the great obscurity which involves the causation of both sporadic goitre and sporadic cretinism. There is no evidence that the subjects of sporadic goitre ever beget either goitrous or cretinous children, or that sporadic cretins are ever the offspring of goitrous or imbecile parents. At the same time sporadic cretins seem always to present some abnormal condition of the thyroid body. In some recorded cases such cretins have been distinctly goitrous; but in a large proportion of them there is an apparent absence of the thyroid body. In Dr. Fagge's<sup>1</sup> cases, in two previously recorded by Mr. Curling, and in some that have come under our own observation, there were soft elastic lumps occupying the angles between the sterno-mastoids and clavicles, which lumps, in Mr. Curling's cases, were found post mortem to consist of fat only. These facts evidently ally the cases of sporadic cretinism to those of the endemic form of the malady, and suggest the dependence of both on a common

<sup>1</sup> 'Med.-Chi. Trans.' vol. liv.

cause; the poison (if it be a poison) being introduced, in the one case constantly and indifferently into the systems of a more or less extensive population, in the other case accidentally, so to speak, into the blood of casual units.

*Treatment.*—The mental condition of cretins, like that of other idiots, admits in many cases of amelioration by proper training; for which purpose a well-ordered asylum with skilled officials is essential. The improvement, far more the cure, of the structural lesions which underlie cretinism is, however, entirely beyond the resources of our art. The prevention of cretinism depends, so far as we know, neither on the prevention of marriage between those who are goitrous or in a condition of semi-cretinism, nor on prophylactic measures adopted with reference to the young children in whom its presence is obvious or merely suspected; but solely on the observance by the parents of those special hygienic measures which are efficacious in the prevention of goitre.

### III. MYXŒDEMA

*Definition and history.*—This is a peculiar disease characterised mainly by the general development of a kind of solid œdema, in connection with a tottering feeble gait, slow and monotonous utterance, slowness of thought and movement, and atrophy of the thyroid body.

It was first described by Sir W. Gull<sup>1</sup> as a ‘cretinoid state supervening in adult life in women’; and has since been investigated and named by Dr. Ord,<sup>2</sup> who extended his inquiries into its morbid anatomy. Sir W. Gull’s suggestion as to the nature of the disease has received remarkable confirmation from the observations of Prof. Theodor Kocher<sup>3</sup> of Berne. He has removed the thyroid body wholly or in part in over 100 cases; and he finds that, of those patients who survived, all in whom the extirpation had been incomplete remained well, while all (excepting certain recent cases) in whom the gland had been wholly removed presented after a time a very remarkable group of symptoms. These symptoms were more marked according to the length of time which had elapsed since the operation, and were most extreme in those who had been operated on before the growth of the body had been completed. He was unacquainted with myxœdema; but his description of the phenomena presented by these cases is the description of myxœdema. His cases seem to prove experimentally the important relations which subsist between the thyroid body and the cretinoid state; and link together in an unmistakable way, myxœdema, sporadic cretinism, and the true cretinism of Alpine valleys.

*Causation.*—Myxœdema, though it has been met with in men, is a disease mainly of women, and of adult age. No cause for it has yet been discovered.

*Symptoms and progress.*—It begins insidiously, and only after some

<sup>1</sup> ‘Clinical Society’s Transactions,’ vol. vii.      <sup>2</sup> ‘Med.-Chi. Trans.’ for 1877–78.

<sup>3</sup> Langenbeck’s ‘Archiv,’ xxix. 2, 1883.

years attains its full development. At that time the condition of the patient is very remarkable. She is probably well-nourished and even fat. There is general œdema, which is more marked in the face and hands than elsewhere; and the skin is for the most part dry and harsh, and the hair often scanty and weak. The œdematous parts do not pit on pressure. The features are thick, the *alæ nasi* tumid, the lips large and pendulous, and the connective tissue round the eyes swollen, translucent, and colourless. The skin of these parts and of the rest of the face is dry, but smooth and delicate-looking; and, although the face has generally a pale and waxy aspect, the lips are rosy, and there is a persistent circumscribed blush upon the cheeks. The hands are large, thick, and clumsy, and, as Sir W. Gull describes them, 'spade-like'—an appearance which is due to the fact that the fingers are thickened, have lost their natural markings and contour, and are pressed and flattened against one another. Her utterance is slow, monotonous, and thick, sometimes squeaky in tone, and is something like that which characterises tonsillitis. She speaks as if her tongue were too large for her mouth, and as if also there were some impediment to the free use of her organs of articulation. The tongue is probably actually larger than natural, and the interior of the cheeks and the soft palate, like the superficial parts of the body, are œdematous. The muscles generally appear to be well developed; but there is manifest feebleness, especially in the lower extremities; she walks with a tottering, uncertain gait, and occasionally her legs give way under her while she is walking, and she falls down. The patient's expression is placid and foolish; and, just as she is slow and deliberate in her speech and walk, so she is slow and deliberate in all her movements and mental processes. It takes her probably twice as long to get through her work, of whatever kind, whether mental or bodily, as it did when she was in health; and her interest in what is going on about her is manifestly diminished. Yet, notwithstanding this slowness of thought and action, there is in other respects no necessary mental incapacity—she keeps her memory and understanding, and probably expresses herself as well as ever she did in speech and writing; and there is no true paralysis of any muscle, no numbness or tingling; she retains the sense of touch unimpaired, and has the full use of her eyes, ears, and other organs of sense. Further, there is not necessarily disease of any important internal viscus; the heart and lungs are healthy, and the urine for the most part normal in quantity and appearance. But the patient usually complains of chilliness, the temperature is often subnormal, and the quantity of urea excreted is generally diminished. In Dr. Ord's two fatal cases, which had been long under observation, albuminuria supervened before death, and apparently caused it. Albuminuria has been observed also in other cases, more especially as the fatal termination approached; and one case under our own care was attended with ascites. Although the patient's mental condition is generally clear, occasionally towards the end of the disease loss of memory, somnolence, delusions, and even dementia supervene. She may also become deaf. The disease appears to be incurable.

*Morbid anatomy.*—The chief condition discovered by Dr. Ord after death was general œdema of the connective tissue, including that of the kidneys, liver, and heart. The œdematous tissue of the skin was examined chemically by Drs. Ord and Charles, and found to contain mucine in comparatively large quantities—ordinary œdematous skin presenting mere traces or several hundred times less. It is from this peculiarity that the name of the disease has been derived. The myxœdematous condition of the kidney closely simulated subacute interstitial nephritis. The brain was healthy. Later investigations seem to show that the connective tissue of the central nervous organs is affected in the same way as the connective tissue of other parts. The thyroid body undergoes atrophy.

*Treatment* can only be palliative.

#### IV. DISEASES OF THE SUPRA-RENAL CAPSULES

The supra-renal bodies are doubtless liable to most of the organic and other lesions to which other organs are exposed; but there are only two such lesions of them which have any clinical interest—namely, tubercle (Addison's disease) and malignant disease.

##### A. Addison's Disease (*Melasma Addisonii*)

*Definition.*—Tubercular infiltration of the supra-renal bodies, together with the remarkable group of symptoms which seems always to be associated with this lesion, constitutes the malady to which the name of 'Addison's disease' is now universally applied. When present in its typical completeness it comprises, in association, tubercular destruction of the supra-renal bodies, general pigmentary deposition in the rete mucosum, and a remarkable form of progressive asthenia which sooner or later ends in death.

*Causation.*—Addison's disease occurs much more frequently in males than in females, and is rarely if ever met with under the age of ten or over fifty. Its first symptoms have often been attributed to local injury; and it is certain that it occasionally appears to supervene on caries of the neighbouring vertebræ.

*Morbid anatomy and pathology.*—Miliary tubercles appear in the supra-renal bodies, as in other organs, and by their increase in number and size, their coalescence, and the degenerative changes which ensue, lead after a while to their destruction. In fatal cases of this disease, the disorganisation of both glands is usually complete. They may be diminished in size, but are usually enlarged, forming nodulated, rounded, or irregular masses which are adherent to surrounding structures by cicatricial tissue. On section they are found to consist of dense, greyish, translucent, fibroid material, in the substance of which opaque, yellow, cheesy nodules of various sizes are imbedded. In some cases, these have undergone earthy infiltration, in some have softened into tubercular abscesses. In a small number of cases fatal with the usual

symptoms of Addison's disease, simple and absolute atrophy of the supra-renals has been observed. There are no lesions of internal organs or tissues which are constantly associated with the supra-renal affection. In a large proportion of cases there is absolutely no trace of any such complication; in about half the total number (or rather less) miliary tubercles have been met with in the lungs, peritoneum, mesenteric glands, and other parts; and in a small, but yet significant, proportion of them caries of the vertebræ has been present. The condition of the skin has a close resemblance to that of a mulatto; and is variously described as yellowish-brown, dark-brown, greenish-brown, or bronze-like. This discoloration, which is more or less general, affects especially those parts of the body which are most exposed, and those which are normally the seat of pigment. Thus while it tints the face, neck, and hands on the whole more intensely than the chest, belly, and legs, it is usually especially dark in the axillæ, areolæ of the nipples, umbilical region, external genital organs, and groins. The extensor aspects of the joints are generally more deeply tinged than the flexor, and the knuckles, therefore, and backs of the hands are darker than the palmar surfaces. The discoloration never presents an abrupt margin, but is occasionally spotty, especially on the face and neck; and is for the most part especially deep upon surfaces which have been blistered or superficially destroyed. Deep cicatrices, on the other hand, tend to remain pallid. Similar brown discolorations may generally be observed along the lines of junction of the lips, and spots and patches of the same kind may often be discovered on the mucous surface of the cheeks, gums, and tongue. The fungiform papillæ are occasionally the special seats of pigmentation. The change of colour is due, as is that of common freckles, or of the negro's skin, to the accumulation of molecular pigment in the cells of the rete mucosum. The hair is said occasionally to share in the general pigmentation.

The relation between the tubercular disease of the supra-renal capsules, the discoloration of the skin, and the remarkable group of symptoms which attend these lesions, is as yet a matter of impenetrable obscurity. It has been suggested that the explanation of the phenomenon lies in the intimate connection which exists between these bodies and the great sympathetic in the abdomen. It has also been suggested that the supra-renal bodies, like other ductless glands, exert some important influence over the condition of the blood, and that it is in the abolition of this influence that the source of the special symptoms of the disease is to be sought. But these are, at all events at present, mere barren speculations. It has never been shown that disease of the abdominal sympathetic induces symptoms resembling those of supra-renal disease; nor that the blood or the excretions in Addison's disease present any constant departure from the healthy state. It seems probable, however, that the morbid condition of the supra-renal bodies is directly or indirectly the cause of all the other phenomena of the disease.

*Symptoms and progress.*—The chief symptomatic phenomenon of Addison's disease is the gradual development of extreme debility, without

commensurate, it may be without appreciable, loss of flesh. The patient observes : that he is less capable than he formerly was of sustained muscular exertion and less disposed for it ; that he cannot walk far without suffering from shortness of breath and palpitation ; and that if he persist in his efforts he falls into a state of prostration, which may continue on him for many hours or for days. Together with these symptoms he suffers from general lassitude and chilliness, and frequent sighing and yawning ; he probably loses appetite, and has occasional attacks of nausea and vomiting. He perhaps also complains of pains across the loins or sacrum, or in the epigastrium and hypochondriac regions. There may possibly be some giddiness and dimness of vision. The heart's action becomes extremely feeble, its sounds perhaps scarcely audible, and the pulse at the wrist small, weak, and sometimes imperceptible. As to rate, it may be normal or quickened, but is often below the average. In the great majority of cases some obvious darkening of the skin goes along with the above symptoms ; sometimes it precedes them, sometimes follows them, sometimes makes its appearance concurrently with them. It is often first observed by the patient's friends, who probably think that jaundice is coming on, or accuse him of want of cleanliness ; but before long it gets quite obvious to the patient himself as well as to those about him. It is first recognised in the face, neck, and hands ; and generally manifests itself on the upper half of the body earlier than on the lower half. The tint gradually increases in intensity, especially in those situations which usually tend to get darkest ; but the degree which it ultimately attains differs greatly in different cases. In some, though obvious, it is slight up to the close of life ; in others the skin acquires the depth of hue of that of a mulatto or negro. In a small proportion of cases no change of colour ever takes place. The conjunctivæ in all cases maintain their normal pearly lustre throughout. The phenomena above detailed are associated with many negative features of significant importance. The skin remains cool, pliable, and normal in texture ; there is no rise of temperature ; the tongue is clean and moist ; and, beyond nausea and sickness, there are no indications whatever of inflammation or organic disease of the chylopoietic viscera ; the bowels are regular ; and the urine is scanty but normal in appearance and constitution, excepting that urea is for the most part largely reduced in quantity.

With the progress of the case the debility increases. This is not always obvious as the patient lies quiet in bed (to which he is probably before long confined), but especially manifests itself in the supervention of alarming prostration after any unwonted effort. The nausea and sickness increase, but are liable to variation, and may even disappear for a while ; they are not unfrequently associated with good appetite. The patient suffers occasionally from headache in addition to his other pains, and complains at times of chilliness—his hands, feet, and nose probably becoming cold and livid from imperfect circulation ; the temperature in the axilla not unfrequently falls a degree or more ; sometimes, on the other hand, it rises one, two, or three degrees ; and, although no actual paralysis may be

present, he is apt to complain of numbness in his lower extremities and to believe that he has lost the use of them. Towards the close of the disease the breath and skin often yield an offensive cadaveric odour; the skin occasionally becomes furfuraceous; the patient grows apathetic, and disinclined to make any unnecessary movement, or even to reply to questions; and, although now and then becoming delirious, usually remains conscious to the last. Death results from asthenia, and is sometimes brought on by a sudden attack of faintness which may be referrible to some apparently trivial exertion.

It has been assumed in the foregoing account that the patient is free from tubercle of other organs or from vertebral caries. The presence of such complications tends to mask the phenomena due to the supra-renal disease. It is important, however, to note that, even in complicated cases, the complications are rarely so extensive or serious as of themselves to cause death, or so engrossing by the phenomena to which they give rise as materially to obscure the diagnosis of the supra-renal lesion. It might, indeed, almost be said that the presence of tubercles in the lungs or elsewhere, or of caries of the spine, should bring with it a thought as to the possible presence of supra-renal complication.

There is unfortunately no reason to doubt that Addison's disease is always ultimately fatal. The duration of the malady is, however, subject to considerable variation. It is probably not possible in any case to ascertain the exact date of the commencement of the disease; there are good reasons, indeed, for believing that the process of supra-renal degeneration is always far advanced before the clinical signs of the affection reveal themselves. Counting, then, from this latter date, the malady is sometimes remarkably rapid in its progress—proving fatal in the course of two or three weeks; while sometimes it is prolonged for several years. More commonly it terminates fatally within a year. It is important, however, to observe: that the progress of patients with this disease is not always uniformly from bad to worse; but that they are liable to attacks of nausea and prostration, so severe as to threaten life, alternating with periods of greater or less duration in which they gain flesh, and seem to be fairly comfortable and hopeful; that many subjects of it doubtless fight against advancing weakness, not admitting themselves to be out of health until possibly one of those sudden failures of the vital power to which they are liable compels them to yield; and lastly, that such sudden seizures may often be warded off by scrupulous avoidance of mental or bodily exertion, exposure to the influence of cold and errors of diet, and thus the patient's life be greatly prolonged. The debility induced by supra-renal disease is in this respect very much like that which attends saccharine diabetes.

*Treatment.*—The cure of Addison's disease is beyond our power; and all, therefore, that we have to do is to endeavour, by counteracting the various secondary phenomena of the disease, to prolong life and render it endurable. It is of the utmost importance to maintain the patient at rest, as regards both mind and body, and to keep him warmly clad and in an apartment of agreeable and moderate temperature. Sickness and irri-

tability of the stomach should be relieved by appropriate remedies ; tonics (the nature of which must be determined by the condition of the patient's digestive organs) should be administered ; and he should be nourished and supported by wholesome and nutritious food, with such a proportion of alcoholic stimulants as may seem to be needed.

### *B. Tumours of the Supra-Renal Capsules*

The various forms of malignant disease are all apt to attack the supra-renal bodies secondarily ; and in rare cases these organs are the seat of their primary development. When the disease is secondary, the supra-renal growths rarely attain a large size, and probably nothing occurs during the whole course of the case to direct attention to them. When, however, the disease is primary in them, they may form tumours as large as a cocoa-nut, which from their size and situation may be easily recognised during life. It would be difficult, if not impossible, to distinguish such tumours from renal tumours ; they occupy, in fact, exactly those situations which tumours originating in the upper part of the kidneys would occupy. They form rounded or lobulated immovable masses, springing from the posterior part of the abdomen, and are usually crossed by the ascending or descending colon, which they push forwards in their growth. Their development is sometimes attended with frequent paroxysms of agonising pain, and always with the emaciation, debility, cachexia, and other phenomena which are associated with the progress of visceral malignant disease ; but never, so far as is known, with the specific symptoms of Addison's disease.

---

## V. DISEASES OF THE SPLEEN

### *A. Congestion*

*Causation.*—Congestion of the spleen is of common occurrence under a large number of circumstances. It habitually takes place during the progress of digestion. Pathologically it is mainly observed : first, in dependence on lesions involving mechanical impediment to the escape of blood from the spleen, such as obstructive cardiac and pulmonary affections, and especially those diseases of the liver, such as cirrhosis, in which the portal vessels are implicated ; and, second, in connection with numerous acute febrile disorders, of which typhus, enteric fever, pyæmia, and malarious affections may be taken as the types.

*Morbid anatomy.*—In congestion the blood accumulates in the small vessels and intervacular blood-passages, and the organ becomes proportionately enlarged. The rapidity with which this enlargement takes place and subsides is remarkable. The congested organ may attain five or six times its original bulk, while retaining its normal form ; and usually becomes, in proportion to the amount of blood which it contains, pulpy,

lacerable, and even diffuent. When the congestion is frequently repeated, as in ague, or long continued, as in portal obstruction, the enlargement tends not only to increase, but to become permanent.

*Symptoms and progress.*—Simple congestion of the spleen rarely, if ever, reveals itself by symptoms, and equally rarely calls for special medical treatment. It can, however, often be recognised during life (if sought for in those cases in which it is liable to occur) by the presence of a manifest tumour in the splenic region. The normal spleen is situated upon the cardiac extremity of the stomach, its convex surface being in contact with the diaphragm, and no part descending below the ribs. Its lowest point is then in close proximity with the anterior extremity of the eleventh rib, from which point upwards a limited area of dulness, due to its presence, may sometimes be detected on the left side of the thorax. The enlarged organ, however, while partly rising into the chest and increasing the area of splenic dulness in that situation, mainly spreads farther and farther into the abdominal cavity, taking a course downwards, forwards, and inwards. In cases of extreme enlargement it may occupy nearly the whole of the left half of the abdomen—extending from the ribs above to the groin below, from the lumbar region behind to beyond the umbilicus, and causing distinct protrusion of the abdominal parietes. A splenic tumour is usually readily movable, sinking and rising with the respiratory movements, and capable of obvious displacement under manual pressure; its sharp anterior edge can generally be readily felt, and found to present the characteristic splenic notch. If symptoms be present they are mainly a sense of weight or tension in the side and tenderness on pressure. Occasionally rupture of the greatly congested spleen takes place; in which case death occurs with some rapidity, either from the escape of blood into the peritoneal cavity, or from peritonitis.

*Treatment.*—The treatment of hyperæmia consists mainly in the treatment of the morbid condition which gives rise to it.

### B. Hypertrophy

*Causation.*—True hypertrophy is for the most part the consequence of long-continued or repeated congestion. It is therefore frequently associated with cirrhosis and other chronic affections of the liver, and is a common consequence of repeated attacks of malarious fever. It is, moreover, a usual complication of rickets. But some of the most remarkable examples of this affection are furnished by persons who have never suffered from any of the above disorders, and in whom there is no history pointing to the operation of any specific cause.

*Morbid anatomy.*—In true hypertrophy, the organ enlarges without undergoing any obvious change in texture; there is a general increase of all its elements in pretty nearly equal proportion; and it acquires a more or less firm fleshy consistence. It is in this condition, and in that associated with leucocythæmia, that the spleen attains its greatest volume, sometimes filling the left side of the abdomen, from the ribs above to the pelvis below, and from the lumbar region behind to some inch or two, or

more, beyond the umbilicus. It may then measure as much as sixteen inches in length, ten in breadth, and five or six in thickness, and weigh ten, twelve, or even twenty pounds. It retains its normal shape.

*Symptoms and progress.*—The symptoms due to simple hypertrophy are vague, and difficult to disentangle from those of other lesions with which they are frequently associated. Persons thus affected often suffer from anæmia, discharges of blood (especially from the gastro-intestinal mucous membrane), and abdominal dropsy; but it is uncertain how far these phenomena depend on the hepatic lesion which so commonly goes along with splenic enlargement, how far on the splenic disease. But, putting such symptoms aside, there is nothing left to indicate the presence of splenic hypertrophy beyond the local phenomena to which it gives rise. The chief of these is the manifest existence of a tumour which presents the characters (before described) of enlarged spleen, is tough and unyielding in consistence, gives to the patient a sense of weight and fulness, especially if he lie upon his right side, and is unattended with pain or tenderness on pressure. A venous hum, of musical character, may occasionally be recognised on the application of the stethoscope over the tumour. The duration of these cases is always uncertain, and often much prolonged. In some instances amelioration or cure takes place under suitable treatment; in some the organ remains stationary, and yet with little manifest deterioration of the patient's health; in many death ensues sooner or later, either from simple anæmia and debility, or from these conditions associated with hemorrhage, dropsy, or some other intercurrent affection.

The *treatment* of hypertrophy must depend largely on the constitutional malady which has given rise to it. If it be a sequel of ague, quinine or arsenic is indicated; if the patient be suffering from rickets, the remedies suitable for that condition must be employed; if there be heart, pulmonary, or renal disease, our efforts must be regulated accordingly. In many cases no such clue is furnished; and we must then have recourse to those remedies which the general condition of the patient seems to suggest; among the more important of which may be enumerated iodine, iodide and bromide of potassium, iron, quinine, and other tonics. The bowels should be kept freely open—if necessary, by the use of mild laxatives.

### C. Inflammation

*Causation.*—Inflammation of the spleen, at least in an acute form, is exceedingly rare, excepting in those cases in which it is due to injury, embolism, pyæmia, or the presence of morbid growths or foreign bodies.

*Morbid anatomy.*—Splenic embolism is most frequently a consequence of valvular disease of the heart. It leads to the formation of wedge-shaped blocks, or masses, which vary in size from a cubic inch or two downwards, are often multiple, and usually abut on the surface of the organ. In the first instance they are mainly hemorrhagic, and distinguishable from the splenic tissue by their darker colour and greater solidity; but soon the colouring matter gets absorbed, and the masses pass through various stages

of reddish-brown, yellowish-brown, and buff colour, until they become almost pure white. Sometimes they soften into a puriform pulp, sometimes undergo suppuration, and sometimes (especially if small) get absorbed, leaving depressed cicatrices behind, in which earthy particles may remain imbedded. The presence of these infarctions generally gives rise to inflammation in the peritoneal surface over them.

Pyæmic formations present much the same characters; but they are usually more numerous and smaller, and their tendency to soften, suppurate, and involve the peritoneum covering them, is much more marked.

Splenic abscesses may result from the above and various other causes, and, like other abdominal abscesses, may acquire large dimensions, and are liable to various terminations. They may open externally through the abdominal walls, or rupture into the peritoneum, or discharge their contents into the stomach, colon, left lung, or pleura. Adhesive inflammation is not uncommon at the surface of the spleen, and occasionally circumscribed suppuration occurs between this organ and some neighbouring part, such as the stomach, diaphragm, colon, or abdominal walls.

*Symptoms.*—In most of the affections now under consideration there is little or nothing special excepting locality to direct attention during life to the spleen as the seat of disease. There may be, and indeed probably always is, manifest increase of size of the organ, together with uneasiness, pain, and tenderness. The pain, when severe, is mainly due to circumscribed peritonitis, and, from the position and relations of the organ, is liable to augmentation during the respiratory movements. The recognition of an abscess will depend on its attainment of such a size as to form an appreciable fluctuating tumour in the splenic region, and on the phenomena which attend and follow the process of pointing and the discharge of its contents. In all these cases, sympathetic vomiting and febrile symptoms will almost certainly manifest themselves, and rigors are not unlikely to supervene. But it is rare for the splenic affection to be so free from complication as to justify us in attributing them to it.

*Special treatment* will only be called for when pain is complained of or when an abscess becomes manifest. In the former case, poultices, fomentations, and leeches are the most useful applications; in the latter the case must be treated as one of hepatic or other internal abscess.

#### D. Tubercle

Tubercles are very common, especially in young children, and in connection with tuberculosis of other organs. The spleen thus affected is usually somewhat enlarged and studded more or less thickly with them. They are frequently miliary and grey, in which case they may be readily mistaken for the Malpighian bodies; usually, however, some of larger size may also be detected which have already undergone caseation, and thus furnish a clue to the nature of the others. Yellow tubercular masses, irregular in form, and varying from the size of a horse-bean to that of a tare, are also not unfrequently discovered, in greater or less abundance. Occasionally they soften into cavities or form abscesses. Filamentous processes

of false membrane, themselves studded with tubercles, are often attached to the surface of tuberculous spleens.

Tuberculosis of the spleen can scarcely be recognised during life. If symptoms attend it, they will be such as to suggest either congestion, abscess, hypertrophy, or some other than tubercular lesion.

### E. *Tumours*

The various forms of malignant disease affect the spleen with different degrees of frequency and in different modes. First, the peritoneal aspect or the connective tissue about the hilum may get involved by continuity in the course of malignant disease of the peritoneum, stomach, or glands in the neighbourhood of the stomach; and then the morbid growth either invades the organ from different parts of its surface, or runs into its substance along the vessels which enter at the hilum. Second, the spleen may have isolated secondary growths developed here and there in its substance. Or, third, it may be the seat of the primary manifestation of the disease. The last alternative is rare.

Most of the different forms of malignant disease fail to cause any great enlargement of the spleen, or to indicate their presence by special symptoms; and consequently the splenic affection is usually overlooked during life. Still such growths, especially if primary, may attain considerable size in that organ, and convert it into an irregular and more or less indurated mass, readily recognisable during life by palpation, and even (in connection with other phenomena) as a malignant growth of splenic origin. It must not be forgotten, however, that tumours of the great omentum, or other parts of the peritoneum in the neighbourhood of the spleen, are apt to simulate splenic tumours and to be mistaken for them. These remarks do not apply to lymphadenoma. In this, as in simple hypertrophy, the spleen undergoes a nearly uniform enlargement; sometimes acquiring gigantic proportions, but still retaining its natural form, and the characteristic features by which an enlarged spleen may usually be recognised. Occasionally, also, in cases of primary sarcoma of the spleen, the infiltrated organ becomes enormously large and yet preserves its form.

The *symptoms* of splenic malignant disease are not usually of much interest or importance. Those which attend lymphadenoma of the spleen will be most conveniently discussed hereafter in connection with those due to the same affection of the lymphatic glands.

### F. *Cysts and Hydatids*

Simple serous cysts are rare in the spleen, and, so far as we know, unimportant. They are occasionally multiple, and associated with the development of numerous similar cysts in the liver and kidneys. In the case of a young man that came under our observation some years ago, a huge cyst, containing at least a gallon and a half of fluid, had become developed in the course of three or four months in the region usually occupied by an enlarged spleen. It was tapped on two occasions at the

interval of a couple of months, and on each yielded a grumous fluid in which only blood-corpuscles could be detected under the microscope. After the second tapping the patient recovered completely; and some years later no trace of tumour could be detected in the abdomen. There was no special reason to regard the cyst as hydatid.

*Hydatids* are more common and on the whole far more important. But their course and the symptoms to which they give rise are identical (excepting in one or two obvious particulars) with those of hydatids of the liver or peritoneum, and need not be particularly considered now.

#### G. *Atrophy*

Atrophy is exceedingly common, and traceable to various causes. In some cases it appears, like cirrhosis of the liver, to be consequent on an interstitial overgrowth of connective tissue; in some, as also occurs in the liver, to the investment of the organ in a dense and slowly contracting fibrous capsule. But, however produced, it is a lesion which so far as we know causes little or no inconvenience and no symptoms by which its existence may be diagnosed.

#### H. *Lardaceous Degeneration*

*Morbid Anatomy.*—The spleen is perhaps more frequently the seat of the lardaceous change than any other part of the body; but it is generally thus affected in association with one or more of the several other organs which are liable to the same change. Lardaceous degeneration first affects the minute arterial twigs and the cells external to them with which they are in relation. It is especially apt to commence in the Malpighian bodies and vessels connected with them. The lardaceous spleen undergoes gradual and uniform enlargement, and may attain dimensions nearly as extreme as those reached by the simply hypertrophied organ. Its capsule is usually smooth and glistening; and on section the organ presents different appearances according to the degree to which the degeneration has advanced. In the earlier stages it exhibits those characters which have gained for it the name of the ‘sago’ spleen. It is thickly studded with greyish translucent rounded masses, which have a close resemblance to boiled sago-grains, and which are separated from one another by a network of still healthy tissue. In the latter stages these rounded bodies have coalesced, and the spleen is involved in its whole extent. In this condition it presents on section a nearly uniform greyish, translucent, glistening aspect, yields little or no fluid on pressure, and takes the impress of the finger like a piece of wax or stiff dough. It is abnormally heavy, and readily lacerable, breaking however with a somewhat vitreous fracture.

*Symptoms.*—Lardaceous spleen is always associated with more or less anæmia or cachexia, and often with dropsy, tendency to hemorrhage, and other symptoms, for the most part indicative of debility. It is never possible, however, to decide to what extent these various symptoms depend on the splenic disease, which is always secondary to grave chronic lesion

of other organs, and generally associated with similar degenerative changes elsewhere ; to what extent they are referrible to these several antecedent or concurrent affections.

*Treatment.*—Lardaceous spleen probably never calls for independent treatment. Our first efforts must be directed to the cure of the lesion out of which the tendency to lardaceous change has arisen ; our next to the improvement of the patient's general health by the exhibition of iron and other tonics, the administration of abundant nutritious food, and attention to those hygienic measures which are generally beneficial in cachectic conditions.

---

## VI. DISEASES OF THE LYMPHATICS

There are probably no organs or tissues of the body the pathological relations of which are more important than those of the lymphatic vessels and glands ; no organs which are more frequently involved in the course of diseases originating in other parts ; none, the proper diseases of which more profoundly affect the general organism. But their affections are, for the most part, so intimately connected with those of other organs, or with so-called 'general' diseases, that the discussion of the latter necessarily involves that of their lymphatic complications. It is needless, therefore, notwithstanding its surpassing interest and importance, to enter at any length upon the subject of the diseases of the lymphatic system.

### A. *Inflammation*

*Causation.*—Inflammation of the lymphatics is, no doubt, sometimes primary, in the sense in which idiopathic pneumonia is primary, and sometimes the consequence of blows or other forms of direct mechanical violence ; in the great majority of cases, however, it arises secondarily to some local inflammation, or is the consequence of some irritant acting through the blood.

*Morbid anatomy.*—If the glands be secondarily affected, those only suffer which lie next above the inflamed area, in the line of the lymphatic vessels. In this case irritating matters, probably the products of inflammation, are taken up by the lymphatics, and conveyed along them until they get arrested in their progress by the glands. During the passage of these matters the vessels sometimes inflame, and their parietes get thickened and vascular, and the connective tissue around them congested and infiltrated ; and thus their course becomes indicated by red tumid bands. Sometimes, indeed, abscesses form along them. On the other hand, lymphatic vessels frequently convey, without injury to themselves, matters which excite violent inflammation in the glands, and ulterior mischief of the gravest character. Inflammation of the lymphatic glands is marked by hyperæmia, succulence, softening and swelling, and an excessive development of cells resembling those natural to the healthy organs.

Suppuration sometimes ensues, and occasionally (especially among lax tissues such as that of the axilla) enormous abscesses result. In some instances the inflammation assumes a chronic character, and ends in the induration, contraction, and atrophy of the glands. The nature of the inflammation, and its tendency in respect of result, differ in accordance with the characters of the local inflammation, and of the specific disorder to which it owes its origin.

*Symptoms and progress.*—The symptoms due to lymphatic inflammation are principally swelling, heat, pain and tenderness in the course of the affected vessels and in the affected glands, with visible hyperæmia in the situation of such as occupy a superficial position, and febrile symptoms of more or less severity. Indeed, the fever is generally severe (apparently out of all proportion to the extent and importance of the inflamed tract), and not unfrequently attended with rigors. Its severity is doubtless due in no small degree to the fact that the inflamed lymphatics are in direct communication with the blood, and are constantly pouring the products of their inflammation into it.

*Treatment.*—For the general treatment of inflamed glands (supposing them to need any apart from the affection to which their inflammation is secondary) no rules need be laid down beyond such as should guide us in the treatment of tonsillitis and other such disorders. For local treatment leeches, fomentations, poultices, and in some cases cold applications, are chiefly important. When the inflammation is chronic, counter-irritants, iodine paint, strong mercurial ointment, and blisters will probably be more efficacious.

### B. *Tubercle. Scrofula*

*Morbid anatomy.*—Tubercular or scrofulous glands have already been described (p. 61); and it has already been shown that they tend to undergo speedy caseous degeneration, and to be converted into opaque, yellowish, friable, fattily-degenerated masses, which, according to their situation and other attendant circumstances, either soften or suppurate, or become converted into encysted mortary or cretaceous masses. Softening with ulcerative destruction takes place especially in connection with mucous surfaces; softening with formation of abscesses, in the case of the glands which are superficially placed; cretaceous changes, in the glands of the mediastinum and mesentery, and others which lie deep in the interior of the body.

*Symptoms and progress.*—The symptoms of tubercular or scrofulous disease of the glands are rarely characteristic except when the affected glands are so situated as to admit of ready examination. They are then as a rule scarcely painful or even tender, and are usually indolent in their progress; suppuration is long delayed and slow to reach the surface; and even after the contents have been evacuated the abscess continues to discharge for an indefinite time; and when at length the cavity heals, the scar which remains is ragged and unsightly. The general symptoms are those of debility and constitutional weakness.

*Treatment.*—The constitutional treatment of scrofulous disease of the glands consists in the use of tonics, cod-liver oil, and good nourishing diet, change of air, and generally careful attention to hygienic measures. The local treatment belongs mainly to the surgeon. So long as the glands are neither painful nor suppurating, it is probably best to trust wholly to constitutional treatment; but when pain or suppuration arises, poultices or fomentations are demanded, and, in the latter case, sooner or later the surgeon's knife.

### C. Morbid Growths

*Morbid anatomy.*—Malignant disease, commencing elsewhere, invariably soon attacks the lymphatics, and in the first instance those glands which lie nearest to the primary spot of disease, between it and the thoracic duct. These glands indeed generally become rapidly and extensively involved, forming large tumours, which sooner or later coalesce with one another, and implicate in the progress of their growth the surrounding tissues. Thus, in malignant disease of the tongue or mouth, the glands at the angle of the jaw first suffer; when the breast is the source of infection, the axillary glands; when the lungs, the bronchial glands; when the stomach or bowels, the mesenteric or retroperitoneal glands; when the penis, the glands of the groin; when the testicle, those lying in the lumbar region. In some cases involvement of the lymphatics forms a still more obvious factor of the disease; and it may be primary. The most remarkable example of this kind is furnished by lymphadenoma, which (as has been before pointed out) affects primarily not only the lymphatic glands but the lymphatic tissues throughout the system, and, though not necessarily limited to these in its ulterior development, commits its ravages mainly upon them.

*Symptoms and progress.*—The constitutional symptoms caused by malignant disease of the lymphatics are mainly those of malignant disease generally; when, however, these organs are implicated, the morbid process has already begun to exert a specific influence over the system, and the so-called 'cancerous cachexia,' if not previously manifest, becomes for the most part rapidly developed. The local symptoms are those of a painful rapidly growing tumour, the direct results of which depend upon its situation.

*Treatment.*—Palliative measures only are as a rule available in malignant disease of the lymphatic glands. Accessible glands occasionally admit of removal with temporary benefit.

### D. Mediastinal Tumours

*Morbid anatomy.*—Tumours are of common occurrence in the mediastina, and are often primary in this situation. It is not always easy to determine in what tissue they have originated. It is certain, however, that they often appear to start from the lymphatic glands in the posterior mediastinum, and from that part of the anterior mediastinum in which are situated the remains of the thymus gland. It is not improbable that

they arise also in the substance of the connective tissue. The nature of the disease varies in different cases ; sometimes it is cancer, but probably much more frequently sarcoma or lymphadenoma. Sometimes it is syphilitic. The growth, especially in the former cases, gradually increases in bulk, and, even if it did not originate in the lymphatic glands, very soon involves them, and by degrees implicates all the surrounding parts. Thus it may invade all the tissues of the anterior and posterior mediastina, surrounding and involving the fibrous pericardium and the adjoining parts of the parietal pleuræ ; or it may involve the roots of the lungs, extending along the bronchial tubes and vessels into the substance of the lungs, or implicating the neighbouring parts of these organs by continuity, and probably constituting large tumours in them ; or it may extend into the cardiac walls, either infiltrating their substance or forming distinct growths. Further, it is apt, sooner or later, to implicate the trachea, bronchi, or œsophagus, the innominate veins or cava, or the recurrent laryngeal nerves ; or to involve the lymphatic glands above one or other clavicle ; or to lead to the development of tumours in the ribs or soft tissues of the thoracic walls. The dimensions which mediastinal tumours attain are sometimes enormous ; they may become as large as an orange, cocoa-nut, or child's head ; moreover, in their growth they tend to cause much compression and displacement of parts. The heart, for example, may be carried into the left axilla, or even into the right. In a case under our care, in which there were malignant tumours in the thyroid body, obstruction of the veins of the head and neck and arms, attributed during life to extension of growth into the mediastinum, was found to be due to a malignant mass, the size of a pigeon's egg, growing from the walls of the superior cava and completely obstructing its channel.

*Symptoms and progress.*—The symptoms to which mediastinal tumours may give rise are necessarily very various, and depend mainly on their seat and bulk and the particular intrathoracic organs which they implicate. They are almost identical, indeed, with those caused by intrathoracic aneurysms. The early symptoms are vague, but not unfrequently include progressive anæmia, debility, and shortness of breath. The more characteristic phenomena slowly supervene—the order of their sequence varying, however, in different cases. Sometimes the veins get obstructed ; those of one-half of the head and neck and face and of the corresponding shoulder, arm, and side of the chest, or those of both sides equally, become dilated, tortuous, and full ; and the implicated regions acquire a ghastly, livid, or congested aspect, and get more or less puffy or œdematous. This limited congestion and œdema are very striking phenomena ; especially when, as generally happens, the rest of the body is pallid and wasted. Sometimes the respiratory organs suffer, and the patient has difficulty of breathing, with cough, and probably expectoration. The symptoms then are either like those of slowly advancing bronchitis ; or, owing to implication of the trachea, or recurrent laryngeal nerve, like those of laryngeal disease, and attended with hoarseness or aphonia, and attacks of suffocative cough ; or, in consequence of the formation of tumours in the lungs or of the super-

vention of pneumonia or pleurisy, like those ascribed to these several affections. Sometimes the symptoms are mainly cardiac, and simulate those due to valvular disease. Sometimes the patient has difficulty or pain in swallowing. And often in connection with cardiac, pulmonary, or laryngeal symptoms, or those of venous obstruction, he complains of vertigo, headache, and even of occasional attacks of momentary unconsciousness or slight convulsion. It is not uncommon to have blood in the expectoration; and late in the disease the sputa are apt to be abundant, muco-purulent, and fetid.

The diagnosis of mediastinal tumours is often largely aided by physical examination: by the gradual extension of the area of præcordial dulness, by the increase of resistance experienced on percussion, by the displacement of the heart or lungs, or by the supervention of pulmonary consolidation or pleural effusion, and the modification in the auscultatory phenomena which these several affections entail. It is further aided by the presence of pencils and knots of dilated capillaries and veins in the thoracic parietes. Important indications are furnished in some cases by the development of tumours in the chest-walls, or above the clavicles; and in a few by a history of syphilis, or the presence of syphilitic lesions elsewhere in the body.

It must not be forgotten that in the course of mediastinal disease secondary tumours are apt to arise in other parts of the organism; and that these occasionally cause more striking symptoms than the primary disease, which may then be overlooked. Thus it is not uncommon in these cases for such tumours to develop in the brain, and for the patient to die of the cerebral complication.

It is obvious that the symptoms of mediastinal growths are made up mainly of those due to implication of the various important organs which occupy the mediastina or abut upon them; and in order that the reader may have a clear conception of their variety and importance, and a thorough picture of the disease, we must refer him to the descriptions elsewhere given of the phenomena referrible to lesions of the several organs here adverted to.

Mediastinal tumours are almost always progressive in their course, and sooner or later fatal. If syphilitic, however, improvement and even recovery may ensue. The causes of death are various.

*Treatment.*—There are no special indications for the treatment of mediastinal tumours, unless there be reason to suspect their origin in syphilis. In this case anti-syphilitic remedies are demanded. As a general rule symptoms must be dealt with as they arise.

#### *E. Obstruction and Dilatation of the Lymphatic Vessels*

*Morbid anatomy and symptoms.*—Obstruction of the thoracic duct may be caused by the pressure of tumours, by disease of its walls, or by a morbid condition of its contents; but is rare. It might be supposed that it would lead to rapid innutrition, and at the same time to general dilata-

tion of all the lymphatics, excepting those of the right upper extremity and corresponding side of the head, neck, and thorax. But experience and experiment alike seem to show: that whilst *sudden* obstruction usually results rather quickly in great over-distension of the lower part of the duct and especially of the receptaculum chyli, which presently ruptures with extravasation of its contents into the retroperitoneal tissue; *slowly induced* obstruction may be compensated for by the enlargement of existing communications between the obstructed left and the still pervious right duct.

Obstruction occurring in a group of lymphatic glands in consequence of disease going on in them, or in a group of lymphatic vessels as a result of pressure upon them or of their involvement in disease, always leads in the first instance to stasis and accumulation of lymph within the tributary vessels, which consequently dilate, and subsequently to similar accumulation within the lymphatic spaces and to their disproportionately large expansion. The lymph-channels, indeed, and the tissues generally, become surcharged with lymph: a clear or milky yellowish alkaline fluid of a sickly odour, which contains albumen, fibrinogen, and lymph-corpuscles, and among other occasional constituents sugar and molecular fatty matter, and which, like the plasma of the blood, coagulates on removal from the body. The result is the development of what is often termed solid œdema or leucophlegmasia of the implicated portion of the body; which becomes swollen and tense, and of a pale waxy aspect, but does not pit on pressure as in ordinary venous dropsy. And, further, if the dropsy be of long duration, and especially if it originated in infancy when the organism is undergoing rapid growth, the affected region (not only connective tissue, but muscles, bones, and skin) becomes distinctly hypertrophic. Obstruction and dilatation of the lymphatics is the essential feature, or an important factor, of several well-recognised pathological conditions. A particular form of enlargement of tongue, usually congenital, in which the organ tends to grow, to protrude from the mouth, and to interfere by its bulk with the growth of the jaws, has been shown by Virchow to be due to lymphatic obstruction. The tongue is honeycombed with dilated lymph-channels, and the seat of consequent overgrowth of all the tissues of the organ, inclusive of the muscular substance and of the papillary surface. The upper extremity has occasionally become, from accidental circumstances, similarly affected. But the most frequent, and, on the whole, the most interesting example of such obstruction and its consequences is afforded by the lower extremity and the adjoining portions of the abdomen and genital organs, in the affection we have already described under the name of elephantiasis lymphangiectodes. The last morbid condition characterised by dilatation of the lymphatics to which we shall refer is elephantiasis Arabum, a disease which, like the last, is more fully discussed in another part of this volume.

*Treatment.*—It is obvious that no medicines are competent to relieve the various consequences of obstruction of the lymphatics: recourse can

only be had to mechanical or operative measures. In enlargement of the tongue, portions of the organ have been excised with benefit; as also have bits of the prepuce when that structure has got hypertrophied.

## VII. LEUCOCYTHÆMIA. (*Leukæmia*)

*Definition.*—By the above term is meant a disease characterised by the presence of an excessive number of white corpuscles in the blood, in association with enlargement of the spleen, enlargement of the lymphatic glands and lymphatic tissues generally, or affection of the medulla of the bones, or these several conditions combined in different proportions. In the present state of our knowledge it is not possible to define accurately the limits of the affection we are about to describe. For: anatomically, lymphadenoma, which we have already described as a form of malignant disease, is scarcely if at all distinguishable from the lesions which occur in typical cases of leucocythæmia; relative excess of white corpuscles is frequently observed not only in cases of anæmia, however produced, but in affections, which are certainly not leucocythæmic, of the spleen and other regions above specified; on theoretical grounds there are reasons for believing that various disorders of the blood-corpuscle-creating tissues might involve similar modifications in the corpuscular constitution of the blood; lastly, cases are undoubtedly met with in which the spleen or lymphatic glands, or both, undergo enlargement like that occurring in true leucocythæmia, in which the symptoms and course of the disease resemble in almost all important respects those of leucocythæmia, but in which the anæmia is unattended with excess of leucocytes. Nevertheless typical cases to which the term leucocythæmia is strictly applicable are frequently met with. In these the spleen is with scarcely an exception the main, if not the sole, seat of specific anatomical change; and it is to this affection that the remarks we are about to make will be chiefly directed.

*Causation.*—The causation of leucocythæmia is very obscure. Dr. Gowers<sup>1</sup> has shown that twenty-five per cent. of cases of the disease presented a history of ague or of exposure to malaria. But certainly that origin cannot be suggested for the great majority of them. Depressing mental and physical conditions have also been assigned as causes. The disease occurs at all periods of life, but is by far most frequent between the ages of twenty and fifty. Men are more liable to it than women.

*Morbid anatomy.*—The most remarkable anatomical fact in splenic leucocythæmia is enlargement of the spleen. This organ attains, indeed, a greater size in this disease than probably in any other. It frequently measures from twelve to fourteen inches in length, and has been met with exceeding eighteen inches and weighing over twenty pounds. Usually it is smooth on the surface, though apt to present a little inflammatory exudation, and retains its normal shape. It is for the most part firm and

<sup>1</sup> 'Transactions of Pathological Society,' vol. xxix

pale, or somewhat mottled on section, and yields less blood on pressure than the healthy organ. On microscopic examination it appears that the enlargement is due mainly to hypertrophy of the splenic pulp, in which there is a large increase both of leucocytes and of fibrous tissue. In about one-third of the cases, according to Dr. Gowers, the lymphatic glands generally or partially are enlarged; and in some of them there is similar enlargement of the aggregations of lymphatic tissue in the bowels and elsewhere. But this glandular affection is almost always a late event in the progress of the disease, and rarely leads to any direct important consequences. The enlarged glands are generally soft, rarely attain the size of a walnut, and present simply an overgrowth of the normal constituents. In a small number of cases the medulla of the bones has been found affected much as it is in some cases of so-called 'pernicious anæmia.' It is for the most part more fluid than natural, variously coloured, and characterised by disappearance of fat, with accumulation of leucocytes and red corpuscles. The liver is often enlarged and fatty. Inflammatory conditions of the lungs and pleuræ, and even of the peritoneum, and dropsical effusions into the connective tissue and serous cavities, are not unfrequently observed post mortem. But even more important and interesting than these is the effusion of blood, which is not only met with in a petechial form under the skin, on the surface of the heart and lungs, and in the substance and on the exterior of the brain, but leads to large and fatal discharges from the mucous surfaces, into the serous cavities and connective tissue, and even into the substance of the brain. The blood, as will presently be shown more particularly, presents a large relative excess of white corpuscles, which after death are not unfrequently found aggregated in pale clots, or thick creamy masses, in the terminal branches of the pulmonary artery, the cavities of the heart, and the systemic vessels.

*Symptoms and progress.*—Splenic leucocythæmia comes on insidiously. In some cases it is the painless enlargement of the abdomen which first attracts attention. In some cases gradually increasing asthenia, pallor, and shortness of breath are complained of for some time before swelling of the abdomen is observed. And occasionally all the other phenomena are preceded by irregularly recurring slight febrile paroxysms, or by repeated hemorrhages, usually from the nose. But under any circumstances the patient gradually gets anæmic, loses flesh and strength, becomes incapable of exertion, short-breathed and liable to palpitation, and the abdomen grows large, solid, and heavy; and then careful examination reveals the fact that the spleen is enlarged, perhaps enormously, extending not only upwards into the chest, but probably downwards to the groin, and across the mesial line of the abdomen. Painful priapism, independent of sexual desire, coming on frequently and lasting for several hours at a time, or even continuously for several days, is an occasional early incident of the disease. The progress of the case is slow, but as it goes on: the patient's languor and debility gradually increase; his pulse becomes frequent—up to 90 or 100; his breath continues short, especially

on exertion or under excitement, and is from time to time deep-drawn or sighing, and often attended with yawning; his tongue remains fairly clean; his appetite is variable, but on the whole probably pretty good; there may be some clamminess of mouth, if not actual thirst; and diarrhœa is liable to ensue; the urine is generally fairly abundant, acid, and loaded with urates, and often contains albumen in small quantity, with hyaline or granular casts; hemorrhages are apt to take place, either into the subcutaneous or subserous tissues, or from the mucous surfaces, more especially that of the nose; and occasionally anasarca, mainly of the lower extremities, and accumulations of fluid in the serous cavities, supervene. Febrile symptoms are sometimes absent from first to last; sometimes the patient is liable to paroxysms, coming on at long and irregular intervals; and occasionally he suffers, either during his whole illness or towards its close, from well-marked hectic fever—the temperature rising during the exacerbations to  $101^{\circ}$ ,  $102^{\circ}$ , or even  $103^{\circ}$ . With this are necessarily associated night sweats and other characteristic features of hectic. Besides hemorrhages and dropsical effusions, other complications are apt to supervene, especially during the later periods of the disease; among which may be enumerated splenic peritonitis, pulmonary or pleural inflammation, and the development of subcutaneous abscesses. Phagedænic ulceration of the gums, not unlike the ulceration in scurvy, has occasionally been noticed; and occasionally also tenderness of the bones. Liebreich first observed, and it is now fully recognised, that retinal hemorrhages are of frequent occurrence. These are for the most part small, but are occasionally large, and occur mainly towards the periphery of the retina. They often present a central white spot or area. Sight is not generally materially affected. The spleen does not necessarily enlarge progressively during the whole duration of the patient's illness; but it often becomes stationary after a while, or even liable to slight variations of bulk. During the course of the disease, the blood becomes progressively poorer and poorer in red corpuscles, and consequently pale; but accompanying this change the white corpuscles grow more and more numerous, not only relatively but absolutely, so that at length they may equal in collective bulk the red corpuscles amongst which they lie, or even equal or exceed them in number. The corpuscles are for the most part of the size of the normal leucocytes, but they are often granular from fatty deposit, and apt, like pus-cells, to present two or more nuclei under the influence of acetic acid. Fibrine is usually increased. But the specific gravity of the blood is lessened. So far as is known, splenic leucocythæmia is invariably fatal (usually within a year or two of its first appearance) either by simple asthenia, or by this in conjunction with the effects of some intercurrent affection, such as loss of blood, diarrhœa, or thoracic inflammation. In no inconsiderable number of cases death has resulted from sudden effusion of blood into the substance of the brain, with apoplectic symptoms.

In the cases described as lymphatic leucocythæmia, in which the lymphatic glands and tissues have been found alone or chiefly affected, the

general symptoms have in the main resembled those assigned to splenic leucocythæmia; but the leucocytes present in the blood have been of smaller size than those observed in the splenic disease, resembling in this respect the normal lymphatic-gland corpuscles.

*Treatment.*—The successful treatment of leucocythæmia appears to be altogether beyond the resources of our art. We can do little if anything beyond treating symptoms as they arise, and promoting the health of the patient by attention to diet, hygienic management, and the exhibition of tonics. Arsenic appears to have had a marked beneficial influence in some cases. Other remedies which have been specially advocated are iron, quinine, cod-liver oil, phosphorus, and iodide of potassium.

---

### VIII. IDIOPATHIC ANÆMIA. (*Chlorosis. Pernicious Anæmia*)

*Definition.*—Anæmia is the name applied to a condition in which there is diminution of the solid constituents of the blood, and in particular of the red and white corpuscles, attended with pallor of the general surface, and of the mucous membranes, palpitation, feebleness and rapidity of pulse, panting respiration, sighing and yawning, headache, restlessness, functional disturbance of the organs of sight and hearing, tendency to faint, and general debility. Idiopathic anæmia is a form of anæmia coming on independently of any organic lesion or specific dyscrasia. Two varieties of it are recognised: the one occurring in young women, which is usually amenable to treatment, and is known as ‘chlorosis’; the other arising under other circumstances, largely fatal, and described by different writers under the names of ‘idiopathic anæmia,’ ‘essential anæmia,’ and ‘progressive pernicious anæmia.’

*Causation.*—Anæmia is a frequent complication or result of many different morbid conditions—of the dyscrasiæ, for example, connected with tuberculosis, malignant disease, syphilis, and malarious affections, and of the more or less frequent and copious hemorrhages which take place under various circumstances from one or other of the mucous tracts.

Chlorosis is especially an affection of young females, from the period of commencing puberty to about twenty-five. Many causes have been assigned for it, such as deficient and unsuitable diet, unwholesome habitations, sedentary habits and want of fresh air, late hours, emotional affections, masturbation, constipation, and especially functional uterine or ovarian disturbances. It may readily be admitted that some of these conditions may be predisposing causes of chlorosis; it is certain that some of them may be consequences of it; but it is by no means clear that any of them can lay claim to being an exciting cause.

The other form of idiopathic anæmia is chiefly met with in men; but it occurs also in children and in women of mature age, especially those in whom menstruation is disappearing. Its causes are if possible more obscure than those of chlorosis. Occasionally it seems to be induced by pregnancy.

*Symptoms and progress.*—*Chlorosis* generally first reveals itself by gradually increasing paleness of the surface, palpitation, breathlessness on exertion, loss of muscular power, and more or less gastrodynia and impairment of the digestive functions, without loss of flesh. To these phenomena, however, many others sooner or later are superadded. The pallor usually becomes extreme, the general surface assuming a white or sallow, wax-like appearance; the face, indeed, may present a greenish tinge, whence the name chlorosis. But the loss of colour takes place in the mucous membranes as well as the skin, and is for the most part strikingly obvious in the palpebral conjunctivæ, in the lips and gums, which become in some cases scarcely distinguishable in tint from the skin itself, and in the ears and finger-nails. Yet, even in advanced cases, a fallacious bloom may appear in the cheeks under the slightest emotional excitement. Palpitation is a prominent symptom, and painfully apparent to the patient herself; it is seldom absent, and is always aggravated either by mental excitement or by bodily exercise; the rapidity with which the heart's contractions succeed one another is sometimes extraordinary, and not unfrequently their rhythm becomes remarkably irregular. The development of abnormal sounds in the heart and blood-vessels, independent of organic lesions, is of common occurrence and highly characteristic; systolic murmurs are to be heard frequently over the situation of the aortic or pulmonic valve, and along the course of the ascending arch and innominate artery, occasionally at the apex; murmurs, coincident with the cardiac systole, may be developed more readily than natural by pressure on the subclavian, carotid, and other large arteries; and, lastly, continuous murmurs, musical in character, and varying from a feeble hissing to a deep droning (*bruit du diable*), may readily be evoked by the pressure of the stethoscope on the veins of the neck, more especially on the right side. The respirations are usually more rapid and shallow than in health, and occasionally become extraordinarily frequent, particularly under the influence of bodily exertion or emotional disturbance; and the patient consequently complains of shortness of breath and inability to exert herself. There is usually impairment of the digestive functions, with uneasiness or weight after food, flatulence, loss of appetite, and pain more or less severe and varying in character, in the epigastric region, between the shoulders, in the left hypochondrium or in some neighbouring part. It is apparently in chlorotic girls that perforating ulcer of the stomach is most common, on which account their dyspeptic symptoms must always be regarded with suspicion and treated with care. The bowels are usually constipated. The urine, for the most part, is abundant, pale, and of low specific gravity. There is not unfrequently leucorrhœa; and although the menstrual function in some cases continues to be normally performed, it is usually at fault: the flow is sometimes regular, but scanty; sometimes profuse or too frequent, or attended with severe pain; most commonly there is amenorrhœa. Trousseau points out, and probably with truth, that the sexual appetite is diminished rather than (as is often asserted) increased. The muscular system becomes generally enfeebled; but the subcutaneous

fat undergoes little or no diminution (sometimes, indeed, becomes increased), so that the patient, as a rule, presents more or less *embonpoint*. Anasarca, especially in the lower extremities, occasionally supervenes in the course of the disease. The nervous phenomena which are apt to attend chlorosis are many and various; there are usually listlessness, inability of application to any pursuit or even train of thought, lowness of spirits, and irritability of temper; usually, also, chlorotic girls complain of neuralgic pains, sometimes in the face and head, sometimes in the intercostal muscles, sometimes in the internal organs or extremities. Singing in the ears is common. Again, they are not unfrequently hysterical, have depraved appetites, or suffer from paralysis or convulsions, or even become maniacal. It is rare for the chlorosis of young women to terminate fatally, or even to lead to the development of tuberculosis or any other organic disease, excepting, perhaps, ulcer of the stomach. Under proper treatment the patient generally recovers in the course of a few weeks or a month, but is liable to have relapses.

*Pernicious anæmia* is characterised mainly by occurring as a general rule in those who from age or sex are not liable to chlorosis, and by its frequently fatal result, in from six months to two years. During life cases of this disease are liable, at any rate for a time, to be mistaken for cases of visceral cancer, undetected hemorrhages from the bowels, Addison's disease without melasma, or leucocythæmia; with the last two of which especially, and with purpura, 'pernicious anæmia' has manifest clinical relations. At first the symptoms are not distinguishable from those of chlorosis; but as the disease progresses and approaches its fatal termination, and the patient's vital powers fail, additional symptoms, not observable or unfrequent in chlorosis, manifest themselves; among which are emaciation, remittent febrile paroxysms, anasarca and dropsical effusions into the serous cavities, and extravasations of blood beneath the skin, from the mucous surfaces, and into the retinæ and internal organs. Patients are apt to complain also of throbbing, either general or limited to the head; of numbness or loss of power in the extremities; of temporary attacks of dimness or loss of sight; of failing memory and inability to concentrate the attention. In some cases the appetite remains fairly good, in some there is frequent nausea or vomiting. The motions present nothing abnormal. The urine, which is sometimes pale and of low specific gravity, is often of normal quantity, colour and density; occasionally we believe it presents a little albumen. The pulse and respirations vary, but are often quickened; occasionally, on the other hand, especially when the patient is quiet or asleep, they become preternaturally slow. The pulse often presents a jerky character, and capillary pulsation may sometimes be observed in the lips. Tenderness in the course of the bones has been noticed in some instances, dependent, it is supposed, on changes in the marrow, resembling those occurring in leucocythæmia. A slight icteric tinge occasionally becomes developed. In some cases considerable enlargement of the spleen may be detected during life. Death usually results from asthenia, and may be hastened by the occurrence of hemorrhages.

It is preceded often by extreme restlessness and panting respiration, and sometimes by coma. Effusion of blood into the substance of the brain occasionally carries the patient off.

*Morbid anatomy and pathology.*—The pathological phenomena of idiopathic anæmia comprise deterioration of the blood, the changes in the tissues naturally resulting from this deterioration, and certain conditions which seem to have a specific relation to the diminution or disappearance of the red corpuscles.

In all forms of anæmia the poverty of the blood in red corpuscles is evidenced by the general pallor of surface and tissues, by the poorness of the blood in colour (well shown by the faintness of the stain produced on a white cambric handkerchief, as compared with the richness of hue given by healthy blood), and especially by the enumeration of the corpuscles by means of the hæmocyto-meter. The greatest loss seems to occur in pernicious anæmia, in which disease it is not uncommon to find the corpuscles diminished by 75 per cent. In a case reported by Laache they fell to 360,000 in the cubic m.m. Other changes also are usually present. The corpuscles often fail to form definite rouleaux. They often present great variety of size; and, while some probably are larger than natural, the majority are smaller. They are often, also, irregular in form, apparently in consequence of some impairment of consistence. Occasionally nucleated corpuscles are observed. In many cases of profound anæmia refractive globular bodies (microcytes), of a bright yellow colour, and looking like drops of oil, are found in greater or less abundance. These are smaller than red corpuscles, and often have not more than one fourth of their diameter. They are probably escaped hæmoglobin in combination with albumen of the plasma, and to be regarded as evidence of disintegration of red corpuscles. In connection with this matter it may be pointed out that the liquor sanguinis in pernicious anæmia is often distinctly tinted with the diffused colouring matter of the blood, and that Dr. Copeman has shown that crystals of hæmoglobin readily appear in it after its removal from the body. In idiopathic anæmia there does not appear to be any material change in the number of white corpuscles; and there is usually no increase in the number of blood platelets or of granular elements. It may be pointed out that although none of the above phenomena can be regarded as special to pernicious anæmia, it is in pernicious anæmia that we find the greatest degree of loss of red corpuscles, and that it is in this affection mainly that microcytes are found, that the liquor sanguinis is tinted with diffused hæmoglobin, and that hæmoglobin crystals are apt to form. A further very important distinction between the blood of pernicious anæmia and that of chlorosis is specially insisted on by Dr. W. Hunter; namely, that while in the latter affection the individual blood-corpuscles tend to be paler than natural, and the loss of hæmoglobin to be relatively greater than the loss of corpuscles, in pernicious anæmia the red corpuscles tend to be more brightly coloured than natural, and the loss of hæmoglobin is relatively much less than that of the corpuscles.

The morbid changes which are common to all forms of profound

anæmia and are due to it, are mainly fatty degeneration of the muscular fibres of the heart, of the smaller arteries and capillaries, of the liver and of the kidneys. In addition to which may be mentioned, hemorrhages into the retina and elsewhere, and their consequences.

The specific changes observed in the tissues are few in number, but (especially in connection with some of the facts above stated) highly suggestive. It appears that in anæmia there is a tendency for the red marrow of bone to increase at the expense of the yellow marrow, and that many nucleated red corpuscles and large corpuscles carrying cells are present therein. These conditions, however, are most marked in pernicious anæmia. In this form of anæmia, moreover, various observers have discovered in the tissues of the liver a considerable excess of iron in the form of pigment, which has generally been attributed to the deposit of iron given medicinally. This point has been very carefully investigated by Dr. W. Hunter, who shows that pernicious anæmia is distinguished from all other forms of anæmia by the fact of this excessive presence of iron; that from seven to nine times as much iron is found in the liver in this disease as in any other similar affection; that the iron is in the form of pigment deposited in the cells of the outer two-thirds of the lobules; and that its presence is revealed by reagents which do not affect iron as it is contained in the red corpuscles. And he argues with great force that this excess of iron, combined (as it appears to be) with albumen, and occupying the special site in which it is discovered, can only be referred to disintegration of the red corpuscles within the portal circulation, and the diffusion of their dissolved colouring matter among the hepatic cells. And further, associating these facts with the facts already adverted to (namely, the relative excess of hæmoglobin in the corpuscles of the systemic circulation, the evidence of the destruction of these corpuscles, afforded by the presence of hæmoglobin in the liquor sanguinis, and the indications furnished by the bone marrow that there is at any rate no apparent falling off in the production of red corpuscles), he comes to the conclusion that pernicious anæmia is due to the more or less continuous excessive destruction of red corpuscles in the spleen or liver, or at any rate within the portal circulation; and, for reasons which we need not now discuss, suggests that this distinction may be caused by some poison manufactured and absorbed from the alimentary canal. He believes, also, as is generally taught, that the anæmia of chlorosis is due to the imperfect and inadequate formation of red corpuscles, and is hence pathologically altogether a different disease from pernicious anæmia; a view which is in entire accordance with the different circumstances under which the two diseases arise, with their different clinical histories, and with the different results of treatment which they present.

Dr. W. Hunter compares pernicious anæmia with paroxysmal hæmoglobinuria, and shows that in both cases the essence of the disease is the undue destruction of the red corpuscles of the blood; but that while in hæmoglobinuria this destruction takes place fitfully in the systemic circulation, and the liberated hæmoglobin is discharged by the kidneys, in

pernicious anæmia the destruction is more or less continuous, occurs only in the portal circulation, and the liberated hæmoglobin becomes deposited in the liver.

*Treatment.*—It is no doubt important in the treatment of chlorosis to obviate all possible sources of ill-health, and especially to secure for the patient change of scene, good air, moderate exercise, early hours, innocent amusement and wholesome diet. But of far greater importance than these is the administration of iron. This metal, indeed, appears to be almost a specific remedy in this disease. Different authorities recommend different preparations; but they are probably all (if given in equivalent doses) equally efficacious. They are generally best administered in combination with some vegetable bitter or stomachic, such as quinine, cinchona, or calumba; and in association with occasional purgatives, such as aloes and myrrh pills, to obviate the obstinate constipation which is so often present. The form in which iron should be given must be determined by the special circumstances of the case. If dyspeptic symptoms are predominant, the tartrate of iron in combination with an alkali and calumba or quassia, may be most suitable. It may even under such circumstances be well to delay the use of iron until some amendment in the condition of the stomach has been obtained by other measures. If menorrhagia be present, the perchloride of iron or the sulphate in combination with mineral acids, may prove especially serviceable. Zinc is believed by some to have similar virtues to those of iron. In a large number of cases the ferruginous treatment cures not only the chlorosis, but the various complications—dyspeptic and uterine—which accompany the chlorosis; but that is not always the case, and just as it is frequently necessary to deal with the dyspepsia directly, so it may be essential to direct our treatment to the cure of the uterine derangement. In so-called ‘pernicious anæmia’ all remedies commonly fail. Tonics and nutritious diet seem to be indicated, and are certainly of use. Arsenic has a special value in the treatment of the disease; and marked improvement is not unfrequent, and recovery occasionally takes place, under its influence.

---

## IX. HÆMOPHILIA. (*Hemorrhagic Diathesis*)

*Definition.*—Hæmophilia is a congenital defect of constitution, characterised by a tendency to uncontrollable hemorrhage even from the slightest wounds or abrasions of surface, and after the most trivial injuries.

*Causation.*—The disease is mainly hereditary, affecting males, however, much more frequently than females. Yet it is curious that the females of ‘bleeder’ families, including even those who are not themselves sufferers, are the chief agents in its propagation.

*Symptoms and progress.*—The condition is congenital, and lasts throughout life; but in some instances seems to undergo some degree of amelioration with advancing years. Its presence is discovered accidentally by the occurrence of profuse hemorrhage from some seemingly inadequate

cause. The prick of a pin, the application of leeches, the extraction of a tooth, breaches of surface of all kinds, are followed by bleeding which lasts for hours, days, weeks, until the patient is blanched, and presents all the usual phenomena of acute anæmia, and until, maybe, death ensues. Hemorrhage may of course take place from any surface; but for obvious reasons it is more frequent from the mucous membranes than from the skin, and at the same time less under control, and consequently more serious. Epistaxis, bleeding from the mouth and throat, hæmoptysis, hæmatemesis, and discharges of blood from the bowels and genito-urinary organs are all liable to occur. Further, small subcutaneous hemorrhages are not uncommon; superficial bruises are readily produced, especially on the limbs; and contusions are apt to be followed by large extravasations of blood into the connective tissue. The neighbourhood of the false ribs, the back, the popliteal spaces, and inner aspects of the thighs, have been signalled as the special seats of such abundant hemorrhages. The periods of the first and second dentition are very dangerous to these patients; and in women the epochs at which menstruation commences and ceases. It is curious that the catamenia are not a source of special danger. Besides anæmia, which in a greater or less degree is a necessary consequence of their malady, bleeders are liable to a kind of rheumatic affection mainly of the larger joints. The duration of life among persons with the hemorrhagic diathesis is necessarily much below the average, and many die in childhood. According to Grandidier one-half of the total number of bleeders die before the completion of their eighth year, and less than one-eighth survive their twenty-first.

*Morbid anatomy* throws no important light on the nature of the disease. It is held that in many cases, at any rate, the skin presents marked delicacy and transparency, the subcutaneous vessels occupy an unusually superficial position, the larger arteries and especially the aorta and pulmonary artery are narrower than they should be, and the walls of the arteries generally are thin and transparent. Partial fatty degeneration of the lining membrane of arteries has sometimes been observed. In the blood itself nothing abnormal has been detected.

Concerning the *treatment* of hæmophilia there is very little to say. Of course it is desirable to prevent bleeders from procreating. And of course also every precaution should be taken against injuries of any kind likely to be followed by bleeding. In the event of hemorrhage, pressure when it is applicable is the most efficacious mode of treatment; but local styptics and the usual internal remedies must be had recourse to in the majority of cases.

---

## X. PURPURA

*Definition.*—Extravasations of blood, in the form of points, petechiæ, vibices, or ecchymoses, are not uncommonly observed beneath the surface of the skin in various diseases, and under many other conditions, and are then often termed purpuric. Not unfrequently these subcutaneous extra-

vasations (especially if due to constitutional disorders) are associated with similar extravasations into the solid organs, and beneath the serous and mucous membranes, and with more or less abundant escape of blood from these surfaces. Such extravasations are common in typhus, small-pox, measles, scurvy, obstructive heart affections, and liver disease, and are also met with in scarlet fever, diphtheria, pyæmia, and embolism. They further occasionally complicate certain skin diseases, more especially some forms of erythema and urticaria, and may be induced by mere exposure to atmospheric influences. But to none of these affections, however severe they may be, can the term purpura be properly applied.

Purpura, in the strict sense of the term (the *morbis maculosus Werlhofii* of the Germans), is the name given to a disorder characterised by such hemorrhages as have been above specified, but unconnected, so far as we know, with any local mischief or general specific disease.

*Causation.*—The causes of purpura, or the conditions under which it arises are exceedingly obscure. It occurs at all ages, but mostly in young children of both sexes. It is frequently observed amongst those who are sickly, underfed, or surrounded by unwholesome sanitary conditions; but it is also met with amongst the robust and healthy-looking, and those whose hygienic and other circumstances appear to be unexceptionable. It is certainly not due to insufficiency of vegetable food, nor has it been traced to any special dietetic default. It is apt to recur; and consequently it is not uncommon to find a child (and apparently a healthy one) having periodical relapses, at intervals of three, six, or even twelve months. A child of six years old, under our care, died of exhaustion in its eighth attack.

*Symptoms and progress.*—Purpura is sometimes ushered in with vague premonitory symptoms, such as lassitude, loss of appetite, headache, and aching in the limbs, lasting from one to perhaps three or four weeks. In many cases, on the other hand, the characteristic lesions suddenly manifest themselves in the midst of apparently good health. The skin becomes studded with circular, deep red, almost black spots, varying from about a quarter of an inch in diameter downwards, which are unattended with any abnormal sensation, are not elevated above the level of the skin, and do not fade on pressure. They are usually most abundant on the lower part of the trunk and the lower extremities, but are by no means confined to these situations: and not unfrequently extravasations take place into the eyelids, and beneath the conjunctivæ and the mucous surface of the tongue, lips, gums, and other parts within the cavity of the mouth. These spots go through the ordinary changes of colour which characterise bruises, and, thus fading away, usually disappear completely in the course of a few days. Successive crops of petechiæ, however, commonly appear from time to time, and thus the disease may be continued for two, three, or four weeks, and sometimes for a still longer period. Larger extravasations (vibices and ecchymoses) are usually associated in a greater or less degree with the eruption above described. But these are generally deeper-seated, present less abrupt margins, are attended with swelling,

and not unfrequently first reveal their existence, as deep-seated bruises do, by the gradual diffusion and coming to the surface of their modified colouring matter. They are not unfrequently the result of mechanical violence. Occasionally there are hemorrhages from the choroidal vessels; and the hemorrhage may be so abundant as to cause blindness. There is always a tendency in these cases (more pronounced in proportion to their severity) for hemorrhages to take place from the mucous surfaces. Thus, there may be epistaxis, bleeding from the gums or other parts within the mouth, hæmoptysis, or bleeding from the stomach or bowels, kidneys or other parts of the urinary tract, uterus or vagina. In many cases the hemorrhage is small in quantity and of little importance; but occasionally it is profuse and frequently repeated.

When the affection is slight, the patient may seem during its presence to be in good general health; more frequently, perhaps, he suffers from a continuance of such symptoms as may have ushered in the attack; sometimes the progress of the case is attended with febrile symptoms of a remittent type; but when profuse hemorrhages take place, the symptoms due to loss of blood get developed. Not only does the patient then become excessively pallid, but his pulse increases in frequency and gets more or less jerking; he has noises in his ears, dilated pupils, indistinctness of vision, with muscæ and headache; he yawns, becomes uneasy and restless, and sometimes falls into delirium, mania, or convulsions. His temperature is sometimes lowered; sometimes, on the other hand, considerably elevated, and may reach  $103^{\circ}$  or more. Death is usually due to asthenia or syncope; but is not very unfrequently referrible to sudden and profuse hemorrhage into the substance of the brain. The milder form of purpura is sometimes termed *p. simplex*; the more severe *p. hæmorrhagica*.

A form of purpura is occasionally met with, in which the eruption (occupying mainly the extremities, and coming out in crops at irregular intervals) consists in the first instance of round or oval rosy wheals, the colour of which does not fade on pressure, and remains after the subsidence of the wheals, until the matter on which it depends is removed by absorption. The spots rarely present the dark, almost black, colour of ordinary petechiæ. The symptoms are apt to be continued for several weeks or even months; and in some cases that have been under our care comprised occasional epigastric pain, and nearly constant hæmaturia. The affection agrees in some respects with Willan's purpura urticans.

*Morbid anatomy* throws little light on this disease. Hemorrhages, similar to those beneath the skin, are sometimes discovered in the subserous and submucous tissues, and less frequently in the parenchyma of various organs, more especially the lungs, heart, and kidneys. Occasionally, as has been above pointed out, large effusions of blood are found in the situations usually implicated in cerebral hemorrhage. In one case under our care effusion of blood had taken place into one of the ovaries; and the lymphatic vessels extending from the broad ligament upwards were distended with blood to the thickness of crow's quills. Extreme

fatty degeneration of the muscular fibres of the heart has been detected in cases fatal from repeated hemorrhage, after long continuance of the disease. The blood seems to present no constant departure from the normal condition. It is curious, however, that Dr. Parkes, in two cases which he examined, detected in this fluid an excess of iron together with a general diminution of the solid constituents. It seems more probable, however, that the primary morbid condition is in the capillary and other small vessels than in the blood, and that the latter escapes into the tissues in consequence of their rupture.

*Treatment.*—The principles of treatment of purpura are as little understood as its pathology. The majority of patients get well in the course of a week or two without treatment. The severer cases are unfortunately apt to go on from bad to worse, whatever treatment be adopted. A certain *primâ facie* resemblance which purpura presents to scurvy has induced a common belief that antiscorbutic remedies (fresh vegetables, citric acid, and potash) are indicated here also. Experience, however, does not confirm the truth of this opinion. Among the remedies which have been chiefly recommended are perchloride of iron, acetate of lead, arsenic, digitalis, turpentine, and gallic and sulphuric acids. If the discharge of blood be profuse, one or other of these drugs may be prescribed; and at the same time the patient should be kept quiet and cool, and should have ice or ice-cold drinks given to him. Hemorrhages taking place from accessible parts may, of course, be treated by local measures. If asthenia be extreme, it may be absolutely necessary to give alcoholic stimulants. On the whole, tonic treatment is indicated in those persons who have a tendency to purpura and in those who are convalescent from it.

## XI. RAYNAUD'S DISEASE<sup>1</sup>

*Definition and history.*—The disease to which the above name may be conveniently and appropriately given was first recognised and described by M. Raynaud, in the year 1862, under the names of Local Asphyxia and Symmetrical Gangrene of the Extremities, and was attributed by him to a more or less persistent spasm commencing in the capillary arteries and extending thence to arteries of larger size. He showed that the affection tended to have a symmetrical distribution; and inferred, therefore, that the vascular contraction was determined by influences emitted from the vaso-motor centres. Since his original paper, other contributions to our knowledge of the subject have been made by him, and more recently by other observers, which tend to confirm the substantial truth of his original observations and to show also that the phenomena which he described are important factors in many different morbid conditions.

*Causation and morbid anatomy.*—1. The simplest form of the affection (which he termed *local syncope*) is that in which from exposure to

cold, as from washing in cold water, a part of one of the extremities becomes, as it is popularly termed, 'dead,' that is white, bloodless, cold, and anæsthetic. This is an affection to which many persons are liable in cold weather, which may attack one or more fingers of one or both hands, or the toes similarly, or may involve the whole hand or foot, or even larger portions of the extremities, or the nose or ears, which is of short duration, and which, when it passes away, leaves no obvious trace of damage behind.

2. In some cases, where the disease is more pronounced or more advanced, the affected parts (owing to stasis of blood in the capillaries and small veins) become dusky, bluish or purple, and sometimes mottled (Raynaud's *local asphyxia*). This condition, which is not necessarily preceded by pallor, may last hours or days, without leading to any organic changes; and perfect temporary recovery usually ensues. Occasionally the coldness and passive congestion become almost or quite permanent in certain situations, and the patient complains of habitual coldness and discomfort in them.

3. Sometimes, and mainly in connection with the state last described, portions of the area in which the arterial circulation is in abeyance actually die. The tips of one or more fingers or toes, portions of the nose or ears, small areas of the general surface, or even the whole of certain digits, or the hand or foot, blacken, shrivel and become gangrenous, and after a longer or shorter period are thrown off.

4. Not unfrequently the parts which are liable to be affected in the modes above described become the seat of an eruption of what looks like erythema papulatum, or urticaria perstans, and which also has a close resemblance to chilblains. This is apt to occur about the knuckles, and elsewhere on the hands or feet, and on the ears and nose. It may also appear elsewhere. The inflamed spots are supposed to differ from chilblains in occurring at times when chilblains are not prevalent, in being differently distributed, and in attacking those who have not hitherto been liable to chilblains. It is probable, however, that there is little if any essential distinction between them. Sometimes blebs, containing a sanguinolent fluid, rise upon the affected parts, and are followed by intractable sores.

5. Again, cases are occasionally met with in which the local defect of circulation leads to more or less permanent nutritive changes. In some, the parts affected (the fingers, for example), become smooth, shiny, and pointed; and the nails, and even the bones, may partake in the atrophic process. The appearances are not unlike what are sometimes observed in scleroderma, or in the so-called 'glossy skin,' resulting from injury to nerves. In some cases, on the other hand, the tissues become swollen, the surface of a mottled dusky-red colour, and uneven or tuberculated, from the presence of a persistent eruption of wheals or erythematous or chilblain-like tubercles, in connection with which, vesicles and blebs, followed by excoriation and scabbing, may be developed from time to time. Fingers, toes, hands, feet, and other regions may be thus affected.

6. There can be no doubt that a peculiar marbling of the surface, effaceable by pressure, due to the presence of small and for the most part rounded anæmic arææ, separated from one another by a network of healthily coloured skin, which has been observed in *tabes dorsalis*, is also caused by spasm of minute arteries connected with the skin ; and there are good grounds for believing that some varieties of purpura, and more especially, perhaps, those in which the purpuric spots are preceded by congested wheal-like elevations, coming out more or less symmetrically and in crops, belong to the same category.

7. Cases of Raynaud's disease in a well-marked form have been recorded by Dr. Southey,<sup>1</sup> Dr. Barlow,<sup>2</sup> and others, in which, in association with the characteristic affection of the circulation in superficial parts, there was more or less well-marked paroxysmal hæmaturia : the hæmaturia tending to come on at the same time as the other affection, being of short duration, and often attended by abdominal pain ; and the urine having the aspect of porter, containing large quantities of the colouring matter of the blood, and presenting a brown muddy sediment, but marked absence of blood-corpuscles.

The various phenomena above described, namely, coldness, pallor or lividity, tendency to special nutritive lesions and to hemorrhages, and gangrene, are all of them common consequences of arterial occlusion. And since their occurrence in Raynaud's disease, and in some allied conditions, is for the most part intermittent or remittent, there can be little doubt that the arterial obstruction causing them in this case is due not to embolism or thrombosis, but, as Raynaud holds, to spasmodic contraction of the arteries connected with the affected regions : spasm varying in degree and duration, involving in different cases the vessels of larger or smaller arææ, and probably commencing in the capillary arteries and thence spreading in the centripetal direction. In one case Raynaud observed actual contraction of the retinal arteries, attended with impairment of vision, occurring in alternation with symptoms presumably referrible to spasm of the arteries of some of the peripheral parts of the limbs. That the spasm is of nervous origin is strongly suggested by the marked tendency to symmetrical distribution of the phenomena of the disease. Occasionally, indeed, symptoms apparently identical with those of some varieties of Raynaud's disease, are doubtless due to peripheral neuritis, and go on to atrophy of muscles, &c. The vascular spasm appears to be largely determined by the influence of cold on the surface of the body ; for not only do the various forms of the disease prevail chiefly, sometimes only, in the colder seasons of the year, but attacks are often definitely induced by exposure to cold, and are warded off by the maintenance of warmth.

*The symptoms* of Raynaud's disease vary in severity, and in some respects in character, according to the extent and degree of the local malady, and to the districts involved. In those cases in which parts of the extremities simply become white and cold and soon recover, the

<sup>1</sup> *Clinical Society's Transactions*, vols. xvi. and xviii., and elsewhere.

<sup>2</sup> *Ibid.*

patient probably experiences only local numbness and coldness, followed, as the circulation becomes restored, by tingling and aching. In more severe or extensive cases, and especially in those in which the affected regions become livid or blue, there is not only coldness with more or less impairment of common sensation, but the patient complains also of tenderness, with aching or burning, and even suffers excruciating agony. Moreover, the attack is apt to come on with general sense of chilliness, shivering, and yawning. Often also, especially if the patient be a child, there is much irritability and fretfulness. The supervention of gangrene is generally attended with subsidence of pain and discomfort; but of course the progress of the gangrene and its extension, and the process of separation of the dead from the living tissues, are attended with constitutional symptoms which are severe and prolonged, or the reverse, according to circumstances. In cases in which there is considerable persistence without much intensity of disease, and in which nutritive lesions follow, the local symptoms are less severe than in the acuter cases, and may often only comprise more or less continuous coldness of parts with some tingling or itching, and there may be no material derangement of health in other respects. In some such cases, however, the patient suffers severely from the sense of tingling or burning, especially when the parts are warm, loses feeling and power, and rapid wasting of muscles ensues. When hæmaturia is present in Raynaud's disease, there is often, if not generally, some abdominal pain or uneasiness; and the symptoms associated with it seem to be identical with those which are characteristic of paroxysmal hæmaturia.
